Lemma 10.

Let σ be a S-empty sphere centered at c, of radius r, intersecting S in two points x and y.

If $\varepsilon < \frac{r}{2}$ and $l \overset{def}{=} \frac{\|x-y\|}{4} \geq \sqrt{\varepsilon r\left(1-\frac{\varepsilon}{r}\right)}$, there exists an S'-empty sphere tangent to S' in two points whose center c' and radius r' are such that

$\left|1-\frac{r'}{r}\right|$ and $\frac{\|c'-c\|}{r}$ are at most

$$\delta = \frac{\varepsilon r}{l^2 - \varepsilon r + \varepsilon^2}.$$

Three Dimensional Geometry
Coordinates.

Distance Formula

$$AB=\sqrt{(x_2-x_1)^2+(y_2-y_1)^2+(z_2-z_1)^2}$$

Section Formulae

The coordinates of the point P which divides the join of $A(x_1, y_1, z_1)$ and $B(x_2, y_2, z_2)$ in the ratio $m:n$ are

$$\left(\frac{mx_2+nx_1}{m+n}, \frac{my_2+ny_1}{m+n}, \frac{mz_2+nz_1}{m+n}\right)$$

by taking $m=n$ we find the coordinates of the mid-point of AB as

$$\left(\frac{x_1+x_2}{2}, \frac{y_1+y_2}{2}, \frac{z_1+z_2}{2}\right)$$

Coordinates of any point on the join of two points $A(x_1, y_1, z_1)$ and $B(x_2, y_2, z_2)$ are

$$\left(\frac{\lambda x_2+x_1}{\lambda+1}, \frac{\lambda y_2+y_1}{\lambda+1}, \frac{\lambda z_2+z_1}{\lambda+1}\right)$$ where

$\lambda \neq -1$. If λ takes only positive real values, we get the coordinates of the points on the segment AB (except A and B).

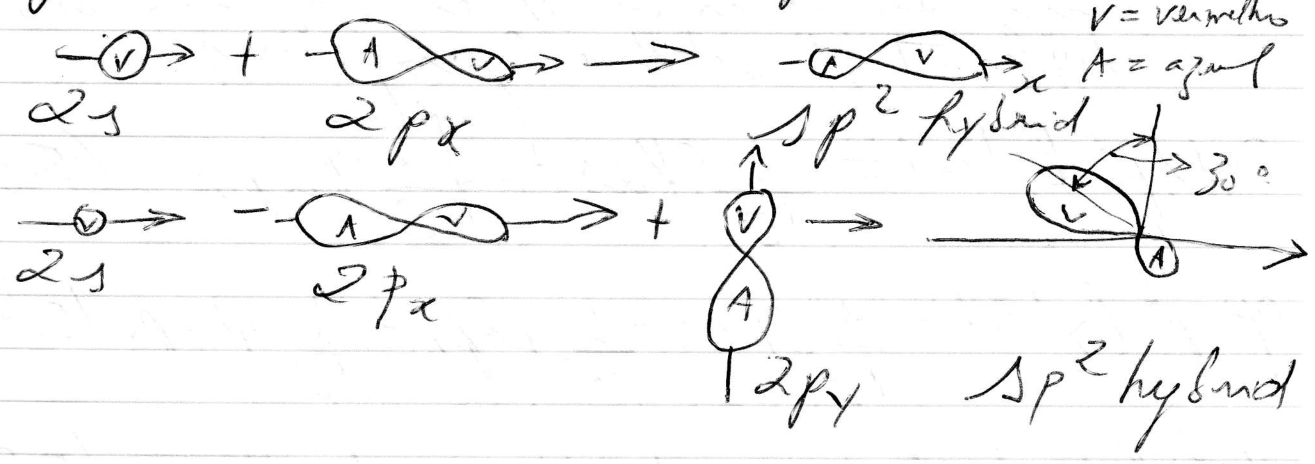
sp Hybridization: a scheme for linear species

The notation sp means that s atomic orbital and one p atomic orbital mix to form a set of two hybrid orbitals with different directional properties.

obs: Fig. 5.1 e 5.2 → shape of the H_2O molecule (interessante)

The model of sp hybridization can be used to describe the σ-bonding in a linear molecule such as $BeCl_2$ in which the Be–Cl bond are of equal length.
The ground state eletronic configuration of Be is [He] $2s^2$ and the valence shell contains the 2s atomic orbital and three 2p atomic orbitals (Fig. 5.3)



→

estudar!!!

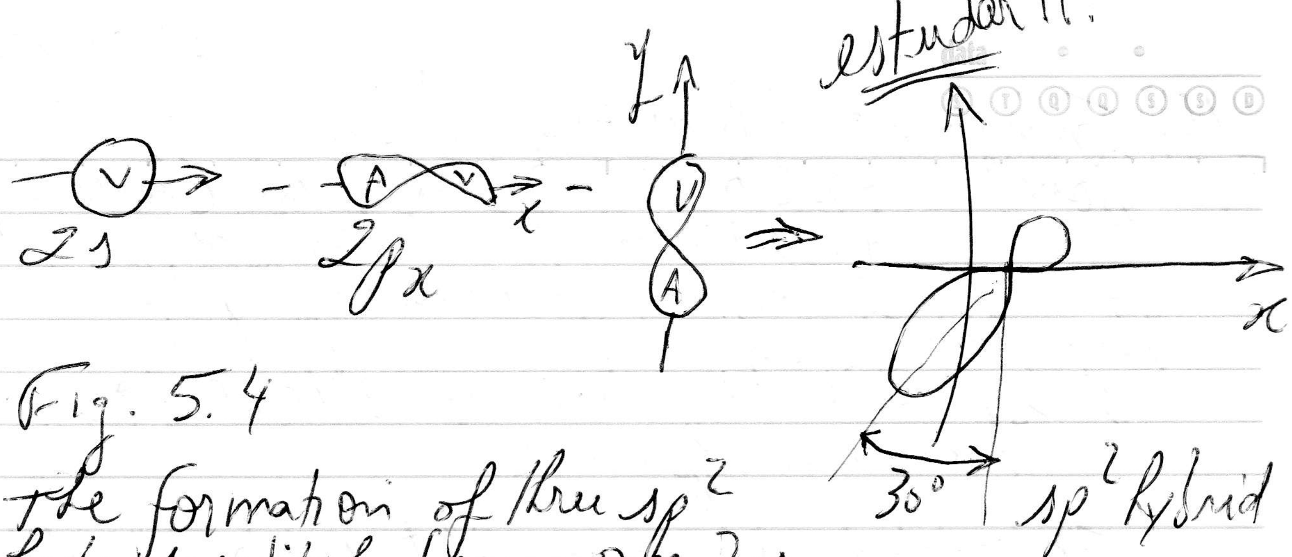


Fig. 5.4

The formation of three sp^2 hybrid orbitals from one 2s atomic orbitals and two 2p atomic orbitals.

Obs: the choice of p_x and p_y is arbitrary. (If we started with $2p_x$ and $2p_z$ atomic orbitals, the hybrid would lie in the ~~xy~~ xz plane; using the $2p_y$ and $2p_z$ atomic orbitals gives hybrid orbitals in the yz plane).

° wave functions (5.3 – 5.5) Pag. 141 [183]

↳ sp^2 hybridization: a scheme for trigonal planar species

sp^2 → the notation sp^2 means that one s and two p atomic orbitals mix to form of three orbitals with different directional properties.

$$\psi_{sp^2\ \text{hybrid}} = \frac{1}{\sqrt{3}}\psi_{2s} + \sqrt{\frac{2}{3}}\psi_{2p_x} \quad (5.3)$$

$$\psi_{sp^2\ \text{hybrid}} = \frac{1}{\sqrt{3}}\psi_{2s} - \frac{1}{\sqrt{6}}\psi_{2p_x} + \frac{1}{\sqrt{2}}\psi_{2p_y} \quad (5.4)$$

$$\psi_{sp^2\ \text{hybrid}} = \frac{1}{\sqrt{3}}\psi_{2s} - \frac{1}{\sqrt{6}}\psi_{2p_x} - \frac{1}{\sqrt{2}}\psi_{2p_y} \quad (5.5)$$

12) Quantum theory of Tunneling

Source: 20190719_04/Quantum theory of Tunneling/jaret.st_981452506.pdf
Pág. XX (21)

In two or three dimensions when the barrier is only a function of the distance from the origin of the coordinate system, i.e. $\rho = \sqrt{x^2+y^2}$ in cylindrical coordinates or $r = \sqrt{x^2+y^2+y^2}$ in spherical polar coordinates we can separate the variables in the Schröndiger Equation and thus reduce the problem to a one-dimensional motion but now with the boundary conditions imposed at $\rho = 0$ or $r = 0$ and at ρ or r going to infinity.

* For instance in three dimensions if we assume that $V(r \to \infty) \to 0$ and that $V(r)$ has a maximum at $r = a$, then if the particle is originally confined in the region $0 \leq r < a$, it can tunnel through the barrier and go to infinity.

These special cases of two- or three-dimensional tunneling can be regarded as one-dimensional but the potentials $V(\rho)$ and $V(r)$ are replaced by $V_{eff}(\rho)$ and $V_{eff}(r)$, with the boundary condition that the reduced radial wave function must vanish at the origin.

Important: Pág. 9 (34) →

2.1. Tunneling and the Uncertainty Principle)

At the first sight the tunneling of a particle looks like a paradoxical problem, since if the height of the barrier is greater that (than) the total energy of the particle

$$E = \frac{1}{2m}p^2 + V(x) \qquad (2.1)$$

then in the range b where $V(x) > E$, the kinetic energy

$\frac{1}{2m}p^2$ is negative and p is imaginary,

but this simple picture is not correct.

$\therefore$ particle can be at the point x where $E < V(x)$ but then according to the uncertainty principle its momentum is uncertain by an amount $\sqrt{\overline{\Delta p^2}}$.

Thus if we know the position of the particle to be x, then its total energy cannot be E.

Position- Momentum Uncertainty in Tunneling (WKB approximation - Chapter 5)

$$\exp\left[-\frac{1}{\hbar}\int_{x_0}^{x}\sqrt{2m(V(x)-E)}\,dx\right] \qquad (2.2)$$

where x_0 is the classical turning point ...

13) Exploratory Galois theory

Source: 20190719_04/Exploratory Galois theory/Swallow J... (2004).pdf

Pág. 3 (17) I Introduction

i is a certain solution to the polynomial equation $x^2 = -1$

obs: π → to see as an infinite sum.

i is a root of polynomial with rational coefficients, and the fact that π is not the root of a polynomial with rational coefficients - in other words, the fact that π is transcendental - means that the methods of studing i are very likely not going to be especially useful in studying π.

Approaching Galois theory, we choose to consider only those numbers that are roots of polynomials with rational number coefficients.

$1/7$ is root of $7x - 1$;

$\sqrt{2}$ is root of $x^2 - 2$;

$\sqrt[3]{-5}$ is a root of $x^3 + 5$;

$\sqrt[4]{20}$ is a root of $x^4 - 20$, and

$11 + 13/\sqrt{17}$ is a root of $x^2 - 22x + (1888/17)$.

We call a root of a polynomial with rational coeffients an algebraic number.

As contribuições de Leibniz para o pensamento da multiplicidade na obra de Michel Serres.
(filósofo)

Autora: Maria Emanuela Esteves dos Santos

21.07.2019 X

Na obra de Serres de 1968 na França,
Le Système de Leibniz et ses modèles mathématiques,
na comparação que ele faz entre Leibniz e Pascal e a questão do ponto de referência.

Pág. 5 (105)

Revista Prometeus - Ano 11 -
Número 26 -
Janeiro - Abril/2018
E-ISSN: 2176-5960

"O recurso à matemática ganha uma nova dimensão quando a geometria arguesiana - isto é, a geometria da infinidade - substitui a geometria finita dos gregos.

"O cálculo infinitesimal invadiu todos os espaços, incluindo a trigonometria tradicional." (Serres, 1968, p. 650).[3]

3 - "um sólido infinitamente grande terá um centro de gravidade indeterminado, bem como o movimento sobre uma circunferência infinita não será centrado, e sim um movimento retilíneo" (Serres, 1968, p. 649).

21.07.2019

Daí, então, a associação entre cálculo infinitesimal e espaço descentrado.

~~68~~) Abstract: heidelberg-laureate-forum.org

The Riemann Hypothesis is a famous unsolved problem, dating from 1859.
A simple proof using a radically new approach.
It is based on work of

von Neumann (1936),
Hirzebruch (1954) and
Dirac (1928).

Pág. 52(69)-

Lambert produced a comprehensive study of the hyperbolic trigonometric functions containing the work of Euler and the Bernoullis (Lambert 1768).

cf: Lambert, J.H. Observations
Trigonométriques.
Pág. 327-354.

Similar developments were made by V. Riccati (1701-75) with Saladini for studying the solutions to cubics.

To define the hyperbolic trigonometric functions, formally introduce a complex variable into the Taylor series for e^x to get:

$$e^{iy} = 1 + iy - \frac{y^2}{2} - \frac{iy^3}{3} + \frac{y^4}{4} - \ldots$$

data 15.08.2019

S T Q [✓ Q] S S D

$$= \left(1 - \frac{y^2}{2} + \frac{y^4}{4} - \dots\right) + i\left(y - \frac{y^3}{3} + \frac{y^5}{5} - \dots\right)$$

$$= \cos y + i \sin y$$

It follows from these formules that:

$$\cos y = \frac{e^{iy} + e^{-iy}}{2},$$

$$\sin y = \frac{e^{iy} - e^{-iy}}{2i} \text{ and}$$

$$\tan y = \frac{\sin y}{\cos y} = \frac{1}{i}\frac{e^{iy} - e^{-iy}}{e^{iy} + e^{-iy}}.$$

By analogy with these formulas, we defined the real-valued functions:

$$\cosh x = \frac{e^x + e^{-x}}{2},$$

$$\sin x = \frac{e^x - e^{-x}}{2}, \text{ and}$$

$$\tanh x = \frac{\sinh x}{\cosh x} = \frac{e^x - e^{-x}}{e^x - e^{-x}}.$$

From the power series, notice that

$$\cos(iy) = \cosh y, \text{ and}$$

Jandaia

data 15.08.2019

$\sin(iy) = i \sinh(y)$.

The fundamental relation for the hyperbolic trigonometric functions is given by:

$$\cosh^2 x - \sinh^2 x = 1.$$

The convergence theorems that support our formal manipulations are classical and can be found in any good complex analysis book, for example,

Complex Analysis, Ahlfors, 1979

Obs:

Fazer estas construções geométricas por meio de equações matemáticas. (Evite usar simuladores ou geradores gráficos pois eles apresentam uma imprecisão inerente ao problema da Quadratura 2D.)

O Circle e foi obtido pela execução de vários triângulos com catetos iguais (mesmo valor) e cuja hipotenusa foi projetada num ângulo de 90° (noventa graus) da ponta do triângulo criado seguindo-se os quadrantes 1, 2, 3 e 4 até o 8 (oitavo) círculo, cujos catetos são 8 unidade de medida.

Vejamos a seguir:

data 19.08.2019

[✓ S] T Q Q S S D

No exemplo em questão:

O triângulo ΔACD, tem as seguintes medidas:

$\overline{AC} = 1$, $\overline{CD} = 1$ e $\overline{AD} = \sqrt{2}$

Deste triângulo básico, projetando-se a $\sqrt{2}$ no ponto D com ângulo de 90° (noventa graus), teremos assim 2 (dois) catetos com o mesmo tamanho cujo valor é $\sqrt{2}$, gerando assim, uma hipotenusa de valor 2.

Desta forma teremos o seguinte:

a)	1	1	$\sqrt{2}$
b)	$\sqrt{2}$	$\sqrt{2}$	2
c)	2	2	$2\sqrt{2}$
d)	$2\sqrt{2}$	$2\sqrt{2}$	4
e)	4	4	$4\sqrt{2}$
f)	$4\sqrt{2}$	$4\sqrt{2}$	8
g)	$8\sqrt{2}$	$8\sqrt{2}$	16
h)	16	16	$16\sqrt{2}$

Finalmente, usando-se o ponto E

que eu vou explicar em seguida:

a) 
→ Fig. I

Circle(E, A):

$$(x-8)^2+(y+8)^2=128$$

Point (origem): E(8, -8)

Obs.: 
Partindo-se deste triângulo retângulo e fazendo a rotação de quadrante (anti-horário). Q1, Q2, Q3 e Q4, usando perpendiculares com a mesma medidas da hipotenusa por 7 vezes, obteremos este círculo C1.

(sete) 7 vezes excluindo o padrão 1x1

guarde este valor.

Obs.: O Ponto C1 é obtido quando o círculo (E, A) $(x-8)^2+(y+8)^2=128$ faz a intersecção com a perpendicular que passa centro do círculo que tem como raio 1 unidade (diâmetro 2).

Para a obtenção dos triângulos, nós deveremos fazer o seguinte:

20.08.2019

No Ponto C_1 trace uma perpendicular que passe por ele e que intercepta a hipotenusa ($\sqrt{2}$), cujos catetos são igual a 1. A intersecção na hipotenusa criaremos o ponto D_1. A distância entre $D_1 C_1$ é $\cong$

0,111805582684409...

Pegando-se este valor como base use-o como divisor do Pi (π) teremos:

$\pi \div 0,11180.... = \underbrace{28},09871008....$

Lembra-se do número 7 que foi armazenado anteriormente, faça a divisão usando-o como divisor.

$28 \div 7 = \underline{\underline{4}}$

Próximo círculo é o $\underline{\underline{8}}$ (oitavo).

$28 \div 8 = 3,5$

$(x-16)^2 + y^2 = 256$

__Obs__: Este círculo se aproxima do eixo $\underline{\underline{Y}}$.

Point for creation E_1 (16,0) e faça círculo com o point A(0,0).

__Important__: O círculo 7 intercepta o centro do círculo 8 no ponto (16,0).

data 20.08.2019

mei 20190818_009_padrão.ggb

1) Criar um círculo de raio 4 unidades (diâmetro 8 unidades) cujo centro é A, faça outro círculo cujo centro é a metade do raio do primeiro círculo.
Todos os círculos estarão um dentro do outro e todos são tangentes ao mesmo ponto D que está fixado do outro lado da circunferência alinhado com o centro da primeira circunferência.

2) Ao todo utilizaremos 5 círculos

Descrição:

a) Point A(0,0)
b) Point B(4, 0)
c) Point C(-2, 0)
d) Point E(-3, 0)
e) Point F(-3,5, 0)

Point G(-3.75, 0)

obs: O círculo com centro no ponto E(-3,0) e raio de 1 unidade no ponto C(-2,0) tem uma área = Pi (π).

Fazendo um estudo sobre perpendiculares que

21.08.2019

passam pelo centro destes pontos descritos anteriormente e que interceptam as suas circunferências (perímetros), criam-se pontos de intersecção e todos estes deverão ser nomeados.

Interligando-se um por um, teremos as seguintes conclusões.

1ª circunferência: Point H(0, −4);

2ª circunferência: Point I(−2, −2);

3ª circunferência: Point J(−3, −1);

4ª circunferência: Point K(−3.5, −0.5);

5ª circunferência: Point L(−3.75, −0.25) e Point D(−4, 0).

Distância:

$\overline{HI} = 2.8284271\ldots = 2\sqrt{2}$

(1/2)

$\overline{IJ} = 1.4142135\ldots = \sqrt{2}$

(1/2)

$\overline{JK} = 0.7071067\ldots = \frac{\sqrt{2}}{2}$

(1/2)

$\overline{KL} = 0.3535533\ldots = \frac{\sqrt{2}}{4}$

$\overline{LD} = 0.3535533\ldots = \frac{\sqrt{2}}{4}$

> =

21.08.2019

Analisaremos os segmentos de reta $\overline{KL}$ e $\overline{LD}$ e suas relações com o círculo e, cuja área é igual a π (Pi).

Salvo como: ARQ/Geogebra_org_2017_versão_6_0_411_02/
20190818_009_padrao_003.ggb.

Observamos o seguinte:

O segmento $\overline{JD}$ é a hipotenusa do triângulo retângulo cujo vértice oposto encontra-se no eixo x, denominado Point E(-3,0).

Desta forma, $\overline{JD} \cong 1.4142... = \sqrt{2}$.

Vejamos o segmento $\overline{JK} = 0.707106...$
($\sqrt{2}/2$)

Obs.: O segmento de reta é a metade ao segmento anterior, mas a área do círculo menor posterior é 1/4 do círculo e

Portanto, o círculo f é 1/2 do círculo e.

Círculo e = π

Círculo f = $\frac{\pi}{4} = 0.7853981633...$

Voltando aos segmentos $\overline{KL}$ e $\overline{LD}$, observaremos o seguinte:

21.08.2019

a) Segmento $\overline{KL} = 0.3535533\ldots \left(\frac{\sqrt{2}}{4}\right)$

Este segmento é a metade do segmento $\overline{JK}$ $(\sqrt{2}/2)$.

b) Segmento $\overline{LD} = 0,3535533\ldots \left(\frac{\sqrt{2}}{4}\right)$.

Somando-se os segmentos

$$\overline{KL} + \overline{LD} = \frac{\sqrt{2}}{2}$$

O círculo menor corta a hipotenusa do círculo maior pela metade, mas a área do primeiro é um quarto do círculo maior.

82) **File:** 20190818_011_V002_001.ggb

Estudar este gráfico:

1) Faça um círculo de raio 4 com origem no Ponto A(0,0) e B(4,0). $x^2+y^2=16$

2) Crie os pontos C(−4,0) e D(0,4).

3) Crie os pontos E(−6,0) e F(0,6)

4) Faço o segmento $\overline{EF}$. (f)

5) Crie uma perpendicular sobre aquele segmento (f) que intercepte o ponto A(0,0). Desta forma, criaremos a Line g: Line through A perpendicular to f.

data 21.08.2019

D S T Q Q S S D

6) Em seguida marque o ponto onde esta perpendicular intercepte o perímetro do círculo c cujo centro é A(0,0) ⇒ Poin G

7) O Point G(-2.8284..., 2.8284...) ou seja,

$(2\sqrt{2}, 2\sqrt{2})$

Neste caso, a distância entre o ponto A(0,0) e G$(2\sqrt{2}, 2\sqrt{2})$ é igual 4.

8) Crie o segmento $\overline{AG}$ (segmento h);

9) Nesta fase de montagem do gráfico, nós temos 2 opções:

a) Criar uma tangente no ponto G em relação ao círculo c.

Line 1: Tangente to c through G.

ou

b) Criar uma perpendicular:

Line: Line through G perpendicular to g.

Obs.: Prefiro esta pois estou interconectando os vários procedimentos de criação entre si.

$6x - 6y = -33.941125496...$

10) Marque os pontos (intersecção) aos eixos Ox e y!

Jandaia

21.08.2019

Point H (-5.656854..., 0) e

Point I (0 , 5.656854...)

11) Crie o segmento HI

Segment j (8 unidades)

Obs.: O segmento AG tem 4 unidades de medida.
O segmento HG tem 4 unidades de medida.
Ambos são catetos,
A hipotenusa AH tem
5.656854...

Import: Criei um arquivo com estes procedimentos:

20190818_011_V003_004_padrão_003.ggb

Criei um novo para continuar o estudo com data de hoje.

20190821_padrão_perpendicular_001.ggb

Prosseguindo!

12) Crie um círculo Circle:d

Circle d: Circle with center G and radius Segment(A, G).

Obs: Ao fazer isso, você estará projetando o segmento AG para a perpendicular

21.08.2019

Line i: Line through G perpendicular to g.

ou seja, $\overline{AG}$ é igual $\overline{GH}$.

O Ponto H está sobre o eixo x pelo qual passa o circle d, a line i, o segmento H, I ($\overline{HI}$).

Podemos adotar uma maior precisão, utilizando uma outra construção geométrica:

Circle through 3 Points

Circle d: Circle through A, G, H.

Desta forma, teremos uma relação mais intrínseca entre estes pontos.

13) Ligue os pontos ~~$\overline{AD}$~~ → $\overline{CD}$.

Criaremos o segmento $\overline{CD}$

Segment k: Segment C, D.

Tamanho: 5.65685424...

14) Com os seguimentos: $\overline{CD}$, $\overline{HI}$ e $\overline{EF}$ vamos criar 3 (três) trapézios que veremos a seguir.

a) Trapézio (Polygon) C, D, I, H.

data 21.08.2019

Este polígono tem 8 unidades de área.

A perpendicular sobre o ponto G $(-2\sqrt{2}, 2\sqrt{2})$ tem o comprimento de 8 (oito) unidades, ou seja, corresponde a aresta maior (base do trapézio invertido) cuja a área também é 8 unidades.

Os pontos G e D geram um segmento que corresponde a hipotenusa decorrente dos catetos iguais de tamanho 4 unidades, que é o raio do círculo original inicial. $(\overline{AB})$

b) Trapézio (H, I, F, E)

Área: ~~0.34314575050~~... 2 unidades

As arestas deste trapézio (arestas menores, laterais) tem o comprimento de

$$0,34314575050\ldots + \overline{CH} \text{ ou } \overline{DF} = 2$$

Obs: Enquanto que no trapézio A a tangente sobre o ponto G, que é o mesmo de uma perpendicular sobre o ponto G, fornece o resultado da área deste primeiro trapézio, que é 8 unidades.

Neste, podemos observar uma mudança da localização do cálculo de área, este passa a ser as arestas menores, enquanto que o primeiro é a base do trapézio A (a).

somando-se as arestas menores do trapézio a e b.

data 21.08.2019

c) Trapézio (Polygon) (C, D, F, E) x

Área: 10 unidades.

Os segmentos (arestas menores do trapézio) $\overline{CE}$ e $\overline{DF}$ têm o comprimento de 2(duas) unidades.

Atualização dos dados salvo em outro arquivo:

20190821_padrao_perpendicular_002.ggb

Ampliando o estudo:

15) Criando um polygon, ou seja, um triângulo retângulo com os pontos A, C, D obteremos a área de 8(oito) unidades.

2(dois) catetos com comprimento de 4(quatro) unidades.

A soma dos dois catetos corresponde à área do triângulo retângulo.

Important: O valor da área ou melhor, o número obtido é igual ao trapézio a (C, D, I, H).
As duas(2) figuras geométricas tem a mesma área.

Observemos que o segmento $\overline{AC}$ (cateto do triângulo retângulo) é 4, 21.08 2019

é o dobro de medida da aresta menor do trapézio a(C, D, I, H).

Extrapolação:

Somando-se os trapézios a(C, D, I, H) e b(H, I, F, E) = trapézio c(C, D, F, E)

a = 8 , b = 2 ⇒ c = 10

Fazendo nova soma com o triângulo retângulo ACD (8 unidades) teremos 18 unidades de área

Multiplique-se por 4 (são 4 quadrantes trigonométricos) teremos

18 x 4 = 72 unidades de área

A Área do círculo c(A, B):

(numéricos)

$x^2+y^2=16$ (unidades de numéricos e não de área).

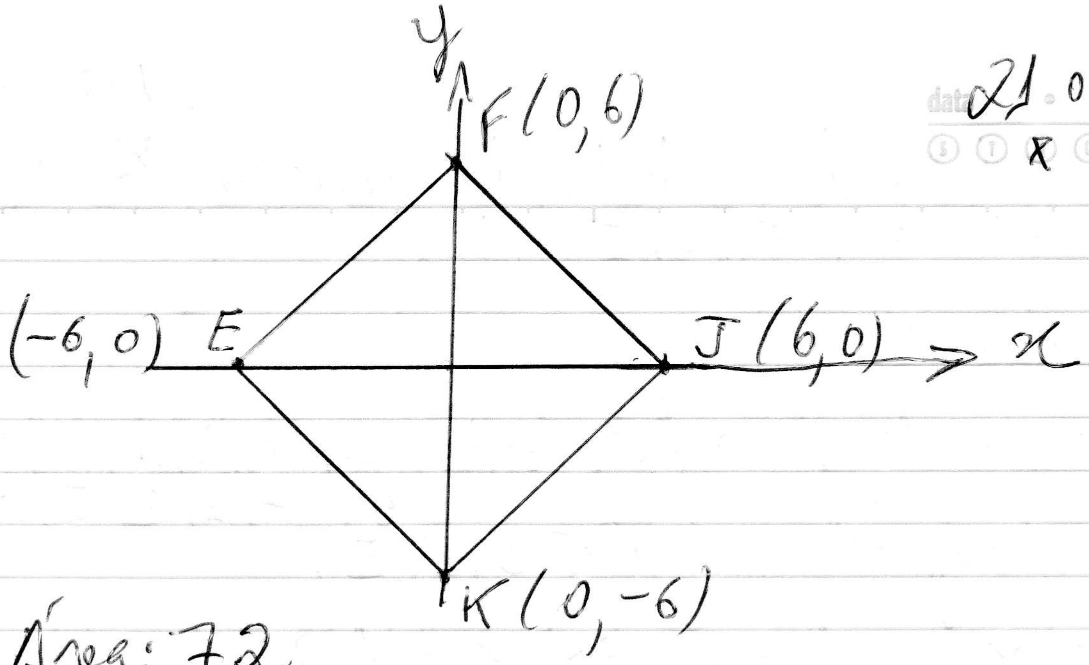
Fazendo a divisão:

72 ÷ 16 = 4,5 vezes.

Portanto o triângulo A, E, F (ΔAEF) tem a área de 18 unidades, mas devemos tirar o trapézio b (H, I, F, E) (2 unidades), assim, nós teremos 16 unidades de área que é igual a área do círculo c ($x^2+y^2=16$)

numérico.

21.08.2019



Área: 72

Os 4 quadrantes do círculo c tem 64 unidades.

O acerto ⇒ 8 unidades = 1/2 do circle c ($x^2+y^2=16$) número.

4,5 vezes

Source:
20190821_padrão_perpendicular_003.ggb

A equação $x^2+y^2=16$ tem uma área de
≅ 50.26548245...

Aprofundando:

64 unidades de área (4 quadrantes) menos o círculo c (50.26548245743669...) é igual à
13.73451754256331

Dividindo-se este número por π (Pi)

21.08.2019

teremos 4,371832715762603556277619...

Subtraia este valor de 4,5 vezes (= ao quadrado □ EFJK).

↳ 72 unidades.

Teremos:

$$0{,}1\underbrace{28167284237396 44}\ldots$$

Se o valor for 5 - 4,371... =

$$0{,}6\underbrace{28167284237396 44}\ldots$$

Ok: Bateu o excesso de 0.5 = 8 unidades de área

72 + 8 = 80 unidades de área.

Important: O valor 0 6281672...é aproximadamente igual

$$\frac{2\pi}{10} \text{ ou } \frac{\pi}{5}$$

↳ 0.62831853071...

Vejamos:

0,5 = 8 unidades em excesso.

De 72 para 80 = $+11.\bar{1}\,\%$

De 80 para 72 = - 10 %

Estudo de área:

data 21.08.2019

S T [✓ Q] Q S S D

Criei o arquivo:

20190821_padrao_area_001.ggb

Seguindo-se ao modelo do arquivo anterior, usando-se por base o círculo c(A, B) de raio 4 ($x^2 + y^2 = 16$) e fazendo-se uma perpendicular no ponto G até esta interceptar o eixo x, teremos a mesma reta (dimensão) de AG.

Em seguida, fazemos o uso do comando

Circle through 3 Points

e ligaremos os pontos: A G H, obtemos o círculo d

$$(x + 2.8284271)^2 + y^2 = \underline{\underline{8}}$$

Área: 25.13274

É metade da área do círculo c (= 50.26548).

Adotando-se estes mesmos procedimentos, nós iremos fazer o 3º círculo:
(seguindo estes passos mais detalhadamente)

1) Observe os pontos onde os 2 (dois) primeiros círculos se interceptam e neste pontos marcaremos os pontos G e L.

21.08.2019

2) Liguemos estes pontos de modo a criar um segmento de reta $\overline{LG}$

Point L $(-2\sqrt{2}, -2\sqrt{2})$

Point G $(-2\sqrt{2}, 2\sqrt{2})$

$\overline{LG} = 5.6568542494\ldots$

3) A reta $\overline{LG}$ (segmento) intercepta o eixo $\underline{x}$ no ponto M

$M(-2\sqrt{2}, 0)$ ↑ criar este ponto.

e neste ponto devemos criar o ponto M com o comando Intersect
(Intersecção)

4) Angle bisector entre $\overline{LG}$ e o eixo x.

5) Què o ponto em que este bisector intercepta o círculo d, criando-se o ponto N $(-\underbrace{4,8284}_{(2+2\sqrt{2})}, 2)$

6) (Circle through 3 Points:
Utilizando-se os pontos: M, N, O)
↳ item $\underline{\underline{7}}$.

No Ponto N, use o comando
Line through N perpendicular to $\underline{x}$
(bisetor)

data 21.08.2019

que criará uma perpendicular que interceptará o eixo x no ponto O

$$(-\underbrace{6{,}8284}_{(4+2\sqrt{2})}\ldots, 0)$$

7) Circle through 3 Points:

Utilizando-se os pontos: M, N, O, criaremos mais um novo círculo. circle r.

A área deste círculo é a metade do círculo anterior (circle d)

circle (M, N, O) →

$$(x + 4{,}8284)^2 + y^2 = 4$$

Área: 12.566370614359183

÷ 4 (da equação)

= 3,1415926...

Continuando no mesmo gráfico, vamos nos ater ao círculo c (A, B)

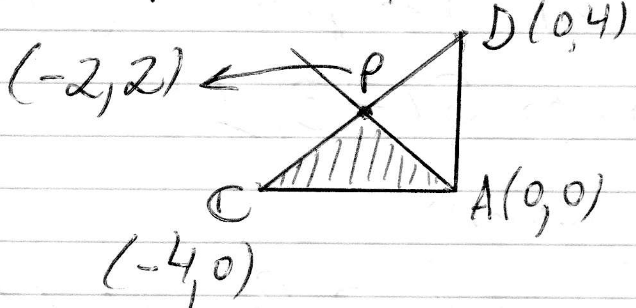
1) Dividindo-se o 2º Quadrante, usando Bisector entre os eixos x e y.

2) Na intersecção deste bisector com o círculo c, criaremos o ponto P (-2, 2)

21.08.2019

Este ponto P ficará entre a intersecção entre o segmento CD e o bisector do ponto A (0,0).

Point C (−4,0), Point D (0,4)



3) Com este triângulo ACD (triângulo retângulo), usemos o comando

Circle through 3 Points.

Cria-se o círculo: $(x+2)^2+y^2=4$

Obs.: Importante. A área deste círculo é igual ao círculo circle r (circle through M, N, O), mas se você continuar a fazer estes comandos dentro do circle c.

4) Criaremos um novo círculo.

a) O Ponto P(−2,2) já existe.

b) O bisector do Ponto A(0,0) intercepta o circle p, (A, P, C) no ponto Q(−2,2).

21.08.2019

c) Ligue os pontos $\overline{PQ}$ (4 unidades)

d) Use o bisector entre o segmento $\overline{PQ}$ e o eixo x, que interceptará o segmento $\overline{CP}$ no ponto S (−3, 1)

e) Crie o ponto S(−3, 1)

f) Com o comando:

Circle through 3 Points (R, S, C)

Criaremos o circle g_1 (R, S, C)

$(x+3)^2+y^2=1$

↳ Área = π (Pi).

Portanto: Este círculo tem o tamanho de 1/4 do círculo anterior.

(0,25).

Important: Da outra forma, a redução é de 50% (1/2)! (fazendo-se do círculo e $x^2+y^2=16$).

Obs: Criei um novo arquivo com estes dados:

1) 20190821_padrão_perpendicular_004.ggb

2) 20190821 padrão_area_002.ggb

83) 201908221440

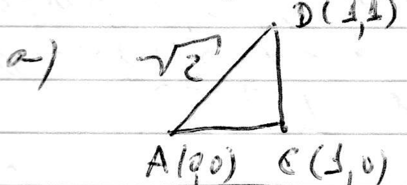
Utilizando o arquivo 20190820_Padrão_001.ggb (original: 20190818_011_v003_004_padrão.ggb).

Acrescente o círculo: (já está no gráfico).

$(x-1)^2+(y-1)^2=2$ Point(1,1)

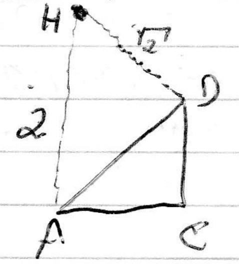
Neste arquivo, o Point D(1,1).

a)



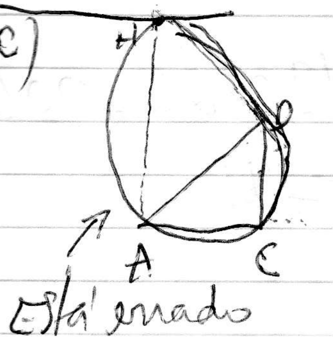
Triângulo retângulo.

b)



Faça a projeção da hipotenusa $\overline{AD}$ sobre a perpendicular incidente sobre o segmento de reta $\overline{AD}$ sobre o ponto D, criando-se o Point H(0,2)

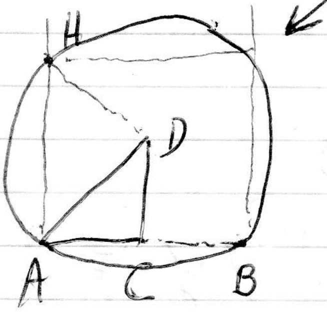
c)



Círculo perfeito! KKK.

Este círculo

$(x-1)^2+(y-1)^2=2$



Ficou melhor!

Use o Circle through 3 points.
(não previa)
Este círculo já está no gráfico.

Faça todos estes procedimentos para o próximo círculo (catetos 2 unidades, hipotenusa $2\sqrt{2}$).

data 22 08 2019
S T Q [✓ Q] S S D

Circle 1: $x^2+(y-2)^2=4$

Faça novamente, com os catetos $2\sqrt{2}$ e hipotenusa 4 (Circle t).

Point$(-2,2)$. = Point F.

Crie o segmento: $\overline{HF}$

Obs: O ângulo entre o cateto e a perpendicular na qual será projetada a hipotenusa do triângulo anterior é de 135°.

Todos estes círculos estão neste gráfico. Esta explanação anterior foi feita para mostrar como eu cheguei aqui, neste modelo.

Resumindo os passos:

Salvo no arquivo: 20190822_001.ggb

1) Circle(A,B) → $x^2+y^2=4$

2) Point C$(1,0)$

3) Point D$(1,1)$

4) Segment $\overline{AC}$, $\overline{CD}$, $\overline{AD}$

5) Circle (C,A) → $(x-1)^2+y^2=1$

↳ Área = π (Pi).

22 08 2019

6) Point E(8,-8)

7) Circle(E, A) → $(x-8)^2+(y+8)^2=128$

↳ Área = 402.12385...

8) Point F(-2,2)

9) Circle(F, A) → $(x+2)^2+(y-2)^2=8$

↳ Área = 25.13274122...

10) Triângulo equilátero ΔABG

Use o comando: Regular Polygon

Marque os pontos A e B e em seguida quantas arestas terá, no caso 3. Neste momento criará o ponto que será nomeado como G (1, 1.7320508075...)
(Atentar para que este ponto intersecione o circle c (A, B).
Obs. Por causa da quadratura acho que não haverá uma interseção perfeita.

11) Point H(0,2) → Intersecção do circle c (AB) e o eixo y.

12) Crie um círculo utilizando os pontos (D, A, H) → $x^2+(y-1)^2=1$

13) Ligue os pontos $\overline{DH}$
Segmento(D, H) → $\sqrt{2}$

data 22.08.2019

14) Segment $\overline{HF} \Rightarrow 2$

15) Point I (-8, 8)

16) Circle(I, A) $\Rightarrow (x+8)^2+(y-8)^2=128$

Obs: Este círculo será usado como parâmetro para estudar as discrepâncias dos cálculos das retas que serão analisadas posteriormente. (simetria entre os pontos I(-8,8) e E(8,-8).)

17) Point J (0.61538..., 0.92307...)

Intersecção entre os círculos AC e círculo AF.

18) Point K (1.1327..., 0.911...)

Intersecção dos círculos AC e EA.

19) Point L (0.8228..., 1.8228...)

Intersecção dos círculos AB e FA.

20) Point M (1.5336..., 1.2836...)

Intersecção dos círculos AB e EA.

21) Crie um novo círculo (D, H)

$(x-1)^2+(y-1)^2=2$

data 22.08.2019

22) Point N (0.8, 2.4)

Intersecção entre os círculos DH e FA.

23) Point O (2.215..., 1.723...)

Intersecção entre os círculos DH e EA.

24) Segment (L, M) → 0.8921...

25) Segment (N, O) → 1.5689...

Important: Até este ponto, observamos a criação de 2 linhas que não são paralelas em decorrência do π (Pi) e da quadratura do círculo. Fazer uma abordagem mais profunda neste aspecto específico.

Fazendo a continuação do nosso estudo.

26) Crie uma linha que ligue os pontos DH.

$\Rightarrow x + y = 2$

27) Line $\overline{LM}$ $(0.5391.x + 0.71080.y = 1.7393...$

28) Line $\overline{NO}$ $(0.6769.x + 1.415 y = 3.9384...$

As linhas (H,D), (L,M) e (N,O) não se entrelaçam de formas distintas no 2º (segundo) quadrante, formando um triângulo obtusângulo.

data 22.08.2019

29) Este triângulo obtuso tem os seguintes pontos:

$\triangle PQR$

$P(-1.5, 3.5)$

$Q(-1.\boxed{8518}..., 3.\boxed{8518}...)$ > estudar!!!

$R(-1.19..., 3.35...)$

obs.: Criado o arquivo

20190822_002_padrão.ggb

84) 20190823

Ideia: 20190820.

$1^1=1$

$1^2=1(?)=2$ por quê?

$2^2=2\times2=4$

Vejamos: $1^2 = \begin{cases} 1\times1=1 \\ 1+1=2 \end{cases}$ → para metro quadrado (área) funciona, mas para números inteiros, não.

recalcular utilizando esta abordagem

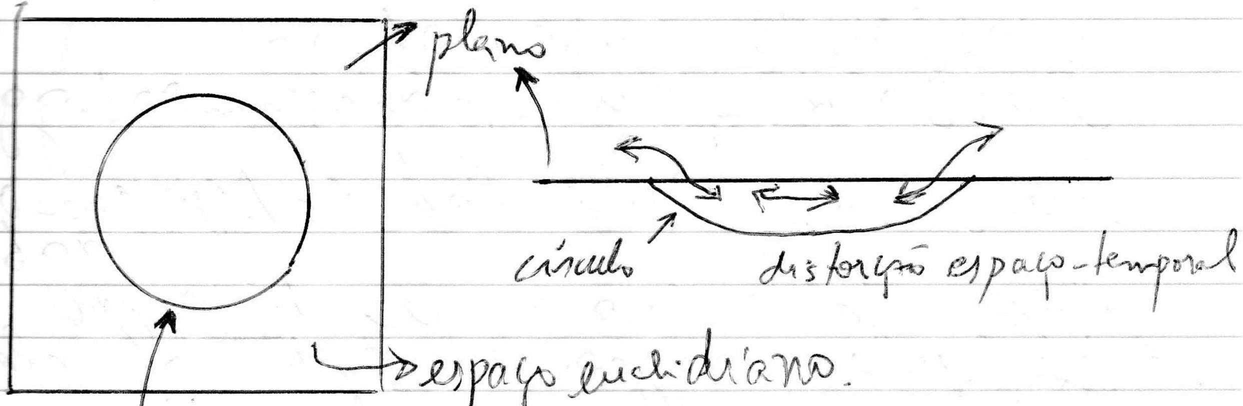
1^2 tem que ser igual (forma) à 2^2. Assim. $2^1=2$ e $2^2=4$. Portanto: $1^1=1$ e $1^2=2$.

(Questão de lógica básica)

23.08.2019

85) 20190823

Solução para a quadratura do círculo.



plano

86) Criei o arquivo:

20190823_Cube_Padrao_Ajustado_003.ggb

Este arquivo tem 2 funções:

- Animação Cube (3D)
- Animação Paralelepipido. (Altera-se a altura do cubo).

Vou criar outro:

20190824_Cube_Paralelepipido_001.ggb

Desenvolvendo

20190824_Cube_Paralelepipido_002.ggb
(ficou incompleto)

Melhorando o arquivo: Paralelepipido_004.ggb

Criando desde do Zero

Passos:

1) Slides a (0, 10, 1)
b (0, 10, 1)
c (0, 10, 1)

d (0, 10, 0.01)

data 24.08.2019

2) A=(0,0,0)
B=(a,0,0)
C=(b,c,0)
D=(0,b,0)

3) Polygon(A,B,C,D)

4) Altere para Perspectives → 3D Graphics
↳ Extrude to Prism or Cylinder
↳ Clique sobre Polygon(A,B,C,D)
↳ Valor: 1.

5) Clique NET e depois sobre o Cube.

Obs: Criado arquivo:
20190824_Cube_Paralelepipido_005.ggb
continuando os comandos:

6) Point1=(0.5, 0.5)
Point2=(-0.5, 0.5)
Point3=(1.5, 0.5)
Point4=(0.5, 1.5)
Point5=(0.5, -0.5)
Point6=(0.5, -1.5)

24.08.2019
X

6) Circle with Center and Radius

Clique nos pontos (um por vez) e o raio usado será 0.5.

Pronto, o padrão está montado.

—

Até aqui:

Paralelipipípido_006.ggb

Paralelepipido_007.ggb
↳ círculos de raio 0.5 são fixados nas arestas dos cubos.

Obs: Veja as simulações dos slides a, b e c.

São construções muito interessantes.

Vejamos:

6 = 7

O círculo central da cruz cresce e toca (tangencia) o círculo da base da cruz, sendo que o círculo intermediário é usado como geratriz do círculo central.
Obs: Nomear ~~logo~~ os círculos.

87) 20190825

File: 20190824_Simulação-Quadrante_001.ggb

Segment $\overline{PQ} = \sqrt{2}$

intercepta o segmento $\overline{LM}$ no ponto L!

O Ponto L também é ponto de interseção com os círculos:

a) Circle c: Circle through B with center A.

b) Circle k: Circle through A with center F.

obs:

circle c: $x^2 + y^2 = 4$

circle k: $(x+2)^2 + (y-2)^2 = 8$.

obs.: Estudar linhas amarelas tracejadas $\overline{QC}, \overline{QT}, \overline{TU}, \overline{UV}$.

Source:
File: Quadrante_002.ggb

Neste arquivo, estes segmentos estão na cor verde.

25.08.2014 X

Observação important:

Segmento $\overline{QC} = 2$

Segmento $\overline{QV} = 2.82842$ $(2\sqrt{2})$

Important:

Estudar também os segmentos

$\overline{QT}$, $\overline{TU}$ e $\overline{UV}$

O segmento $\overline{QT}$ está saindo do cateto do triângulo e não da hipotenusa, de onde deveria se projetar perpendicularmente para que se pudesse calcular o outro cateto para gerar uma nova hipotenusa.

No caso, a hipotenusa $\overline{QC}$ criará um novo cateto perpendicular a este segmento.

Estudar o método tradicional e esta nova alternativa.

obs: Cateto 2 e Cateto 2 = hipotenusa $2\sqrt{2}$.

File: Quadrante_003.ggb

Light Deflection (cont.)

Even earlier:

c) John Michell (1783)

d) Pierre-Simon Laplace (1796)

independently investigated light being subjected to gravity, but in the context of a body

data 08.09.2019
8

acting on the very light it emits.

The both basically arrived at a notion (notion) resembling a "black hole", that is, a sufficiently massive star can capture its own light, leaving the star invisible.

Michell and Laplace did not write about the situation of light coming from a distant source and undergoing deflection as it passes near a gravitating body.

They are who inspired the works of Cavendish and von Soldner

Soldner:

"Thus when a light ray passes by a celestial body, it will, instead of a going on in a straight direction, be forced by its attraction to describe a hyperbola whose concave side is directed against the attracting body."

He showed that a light grazing the sun would be deflected by

0.84 seconds of arc.

(Constante de Avogrado)

$1 m$ = distance light travels in $\frac{1}{299.792.458}$ s

light speed = 299,792,458 m/s

data 24.09.2019

S [✓ T] Q Q S S D

2) Balança de Watt para definir a constante de Planck. (Kibble).

2011 → definiu-se Kg baseado na constante de Planck

Planck's Constant (h)
Avogadro's Number (N_A)

$mg = BLI$

(campo magnético) e comprimento do fio da bobina.

O movimento induz um tensão na bobina que é igual ao campo magnético.

X o comprimento do fio da bobina,

X sua velocidade.

Equações:

$V = BLv$ $IBL = mg$

⟹

data 24.09.2019
S [✓ T] Q Q S S D

$$\frac{V}{v} = BL \qquad BL = \frac{mg}{I}$$

$$\frac{V}{v} = BL = \frac{mg}{I} \Rightarrow \frac{V}{v} = \frac{mg}{I} \Rightarrow$$

$$VI = mgv$$

↳ tensão x intensidade da corrente = massa x aceleração de gravidade x velocidade

Lado esquerdo: potência elétrica — Lado direito: potência mecânica

equilíbrio

Mudando disso para a constante de Planck, o número que relaciona a frequência de um fóton com sua energia?

A tensão pode ser medida acuradamente usando um efeito quântico macroscópico que envolve junções Josephson (Efeito Josephson).

data 24.08.2019

Junção Josephson

consiste em 2 supercondutores separados por um pedaço fino de isolante.

Você aplica uma radiação de microondas a essa junção usando uma tensão em todo o dispositivo e seu valor é precisamente conhecido por ser

$$V = \frac{hf}{2e}$$

h = constante de Planck

f = freqüência da radiação

e = carga em um elétron

Empilhando $\underline{n}$ → number of junctions (em série)

$$V = n\frac{hf}{2e}$$

Essas junções são colocadas no circuito com a bobina, como é movido pelo campo e assim, você equilibra exatamente a tensão induzida na bobina usando essas junções Josephson

⇒

data 24.09.2019

$n\frac{hf}{2e}$ $\qquad$ $n\frac{hf}{\cancel{2e}\,e} \leftarrow (2e)$

$$VI = mgv \Rightarrow$$

$$V\frac{V}{R} = mgv$$

A corrente é passada através de um resistor e nós medimos essa tensão novamente usando junções Josephson

Para medir a resistência, usamos outro efeito quântico macroscópico chamado de efeito Hall Quântico.

A medida da resistência será uma fração inteira

$$\boxed{\frac{1}{p}\frac{h}{e^2}}$$

↳ carga do elétron

Substituindo tudo, teremos h (constant Planck)

$$h = \frac{4}{pn^2}\frac{gv}{f^2}m$$

↳ frequência

Alcance 10 ppb (partes por bilhão).

Vejamos os termos.

24.09.2019

V = velocidade da bobina à medida que este se move através do campo magnético

Para medir esta velocidade usamos um interferômetro à laser
(interferometer)

À medida que a distância à bobina muda as franjas de interferência passam por um detector.

Quantas franjas passaram em um certo período de tempo podemos determinar a velocidade da bobina.

g = usamos gravímetro

data 05.10.2019
S T Q Q S [✓ S] D

f) Einstein space (4.3)

Einstein space is defined as a space which is homogeneous with regard to the Ricci tensor R_{ij}.

Thus, a space for which

$R_{ij} = \lambda g_{ij}$; λ = invariant at all points at every point of the space, then that space is called

Einstein space.

Inner multiplication of g^{ij} shows that

$$g^{ij} R_{ij} = \lambda g^{ij} g_{ij} \Rightarrow R = \lambda N$$

Thus for an Einstein space,

$$R_{ij} = \lambda g_{ij} = \frac{1}{N} R g_{ij}$$

Hence, for an Einstein space Eq. (4.56) holds at every point of the space.

i) 1.1.1. Three-dimensional vectors.

Source: 20191005/Important/Ibragimov-Tensors and Riemannian Geometry (2015, De Gruyter).pdf

Pág. 03(12)

Vector Algebra

$a \in \mathbb{R}^3$ be a three-dimensional (in particular, two-dimensional) vector.

Graphically, a is a directed line segment. Its' magnitude is denoted by $|a|$.

The scalar product $a.b$ of vectors a and b is a scalar quantity (i.e., a real number) defined by

$a.b = |a||b| \cos \theta$, where $\theta \ (0 \leq \theta \leq \pi)$.

05.10.2019

is the angle between the vector a and b.
The scalar product is denoted in the literature by (a, b).

The vectors a, b $\in \mathbb{R}^3$ can be represented in the rectangular Cartesian coordinates in the form

$a=(a^1, a^2, a^3)$, $b=(b^1, b^2, b^3)$,

which means that

$$a = a^1 i + a^2 j + a^3 k.$$

$(a^1 i)$

$$b = b^1 i + b^2 j + b^3 k.$$

where i, j and k are the unit vectors along the first, second and third coordinate axes in $\mathbb{R}^3$, respectively.

Then the scalar product is given by

$$a.b = \sum_{i=1}^{3} a^i b^i.$$

~~1(1915)~~ j) Brans-Dicke theory

Source: https://en.wikipedia.org/wiki/Brans-Dicke_theory

05.10.2019
X

In theoretical physics the Brans-Dicke theory of gravitation (Jordan-Brans-Dicke theory) is a theoretical framework to explain gravitation.

It is a competitor of Einstein's theory of general relativity.

It is an example of a scalar-tensor theory, a gravitational theory in which the gravitational interaction is mediated by a scalar field as well as the tensor field of general relativity.

$$\tilde{x} \simeq x + \theta y + O(\theta^2)$$

$$\tilde{y} \simeq y - \theta x + O(\theta^2)$$

In this infinitesimal limit, the rotation matrix $R(\theta)$ can be written in terms of a matrix r

$$R(\theta) \simeq I + \theta r + \dots,$$

$$r = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \qquad (1.31)$$

Obs: Using of rotations preserve the Euclidean metric with Gyrocommutative Gyrogroups,

I will be able to develop a new glimpse.

Curvature of Plane Curves.png

Osculating → Osculate

Verb:

(of a curve or surface) touch (another curve or surface) so as to have a common tangent at the point of contact.

Should the students be asked to sketch the osculating circle to a given curve at a given point, and then notice that as the point of contact changes the radius of the circle is inversely proportional to the measure of curvature?

If seven points on a twisted cubic be joined, two and two, by twenty-one lines, then any seven planes that contain these 21 lines will osculate a second cubic curve.

Book: A history of non-Euclidean geometry
B. A. Rosenfeld

data 02.02.2020

Pág. 280 (292) - Chapter 8

The Curvature of Space

Curvature and Intrinsic Geometry of a Surface in the Works of Euler

$$K = \frac{d\alpha}{ds} = \lim_{\Delta s \to 0} \frac{\Delta \alpha}{\Delta s}$$

K is also the reciprocal of the radius of curvature at the point in question, that is, the radius of the OSCULATING circle at that point.

(The osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P.)

The concepts of the curvature of a curve and of the osculating circle were already know to Leibniz.

Figure 3.8 Le théorème de Newton affine.

Affine Adjetivo: allowing for or preserving parallel relationship

"still to be implemented are geometric primitives and affine transformation of image".

The simplest way to see why this assertion is true is to observe that any triangle in the plane can be mapped by an invertible affine transformation to an equilateral triangle.

Using parallelograms ~~from the previous~~ to define affine transformations may be a mixed blessing.

It can be obtained from the previous description by applying affine transformation to keep the polygon bounded as it degenerates.

Our interest is in the space of affine equivalence classes of equal-area polygons.

A twisted cubic curve → subject of Atiyah's first paper.

Michael Atiyah and Friedrich Hirzebruch, the creators of topological K-theory.

September 2018, at the 2018 Heidelberg Laureate Forum, he claimed a simple proof of the Riemann hypothesis, one of the most important and challenging problems in mathematics.

His claims have been met with skepticism by the mathematical community.

data 08.02.2020

S T Q Q S [✓ S] D

Twisted cubic is a smooth, rational curve $\mathbb{C}$ of degree three in projective 3-space. $\mathbb{P}^3$.

It is a fundamental example of a skew curve.

It is essentially unique, up to projective transformation.

—

Twisted Cubic

is most easily given
parametrically as the
image of the map

$$\nu : P^1 \to P^3$$

which assigns to the homogeneous
coordinates $[S:T]$ the value

$$\nu : [S:T] \to [S^3 : S^2T : ST^2 : T^3].$$

08.02.2020

In one coordinate patch of projective space, the map is simply the moment curve

$\nu: x \Rightarrow (x, x^2, x^3)$

that is, it is closure by a single point at infinity of the affine curve (x, x^2, x^3).

Homogeneous coordinates
or
projective coordinates

Möbius in 1827 work

Der barycentrische Calcül.

→ points at infinity can be represented using ~~ffinite~~ coordinates.
(finite)

Formulas involving homogeneous coordinates are often simpler and more symmetric than their Cartesian counterparts.

in general, projective transformations to be easily represented by a matrix.

Pág. 207 8. Curvature I:
The Riemann
Curvature Tensor

Grossmann soon found that this problem had indeed addressed and solved in the mathematics literature, in particular by RIEMANN (generalising work of GAUSS on curved (surfaces)), RICCI-CURBASTRO and LEVI-CIVITA.

It was shown by them that there are indeed non-trivial tensors that can be constructed from (ordinary) derivates of the metric.

These can then be used to write down covariant differential equations for the metric. 18

A) Dancing with a black hole

Source: www.nytimes.com/2020/04/16/
science/black-hole-sagittarius-
a.html

Einstein → gravity to a warping of the geometry of space and time.

In our solar system, astronomers had long known that the planet Mercury behaves like this; its perihelion advances around the sun by the microscopic amount of 43 seconds of arc a century.

Astronomers couldn't explain why. In November 1915, Einstein tried out his new theory on Mercury's motion.

data 16.04.2020

B) A star orbiting the Milky Way's* giant black hole confirms Einstein was right

source: www.sciencenews.org/article/star-orbiting-milky-way-giant-black-hole-confirms-einstein-was-right
by Emily Conover
20200416

⇒ Decades of observations revealed the rotation of the star's elliptical orbit.

1915 - Einstein realized that his newly formulated general theory of relativity explained a weird quirk in the orbit of Mercury.

Star S2.

The researchers previously had used observations of S2 to identify a different effect of general relativity, the reddening of the star's light due to what's called gravitational redshift (SN 7/26/18).

Emily Conover

www.sciencenews.org/article/star-orbiting-black-hole-einstein-gravity-general-relativity

data 16.04.2020

Now, they've determined that the ellipse rotates over time, what's known as Schwarzschild precession. That precession is the result of the warping of spacetime caused by massive objects, according to general relativity.

c) Stephen Wolfram's hypergraph project aims for a fundamental theory of physics

Source: www.sciencenews.org/article/
stephen-wolfram-hypergraph-
project-fundamental-
theory-physics
April 14, 2020
by Tom Siegfried

→ causal invariance.

Thanks to causal invariance Wolfram's hypergraphs reproduce many of the consequences of various physical theories, such as Einstein's special theory of relativity. Traveling rapidly slows down time (as special relativity says) because hypergraph structures corresponding to moving objects make an angle through the hypergraph that extends the distance between updates (or time steps). The speed of light is a

16.04.2020

maximum velocity, as relativity states, because it represents the maximum rate that information can spread through the hypergraph as it updates. And gravity — described by Einstein's general theory of relativity — emerges in the relationships between features in the hypergraph that can be interpreted as matter particles. (Particles would be small sets of linked points that persist as the hypergraph updates, something like "little lumps of space" with special properties.)

supersmall unknown particles, which he calls oligons

Such oligons, subject only to gravity, would now be hanging out in and around galaxies utterly unnoticed — except for their gravitational impact.

Oligons might therefore explain why astronomers infer the existence of vast amounts of invisible "dark matter" in space.

"right rule"

That "right rule" would generate a hypergraph with our universe's precise properties:

data 16.04.2020

- three (apparent) dimensions of space,
- the right cosmic expansion rate,
- the right repertoire of elementary particles with the correct charges and masses, and other features.

They are orthogonal when this angle is zero.

For cells in the higher dimensional case, we are looking at the angle between a and the normal $b^{\perp}$ of $b = a^*$, illustrated for dimension $n = 2$

(image)

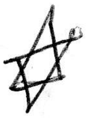
Dually, this angle can also be understood as the angle between the normal

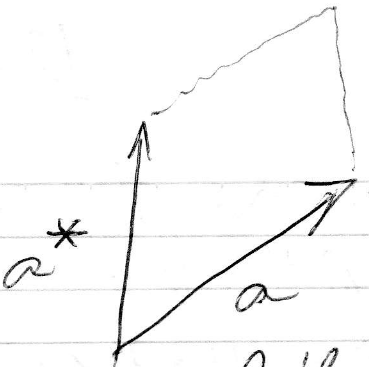
$c = a^{\perp}$ of a and a^*, illustrated for dimension $n = 3$.

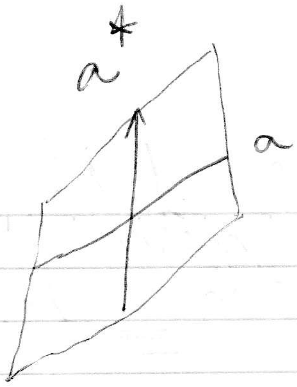
(image)

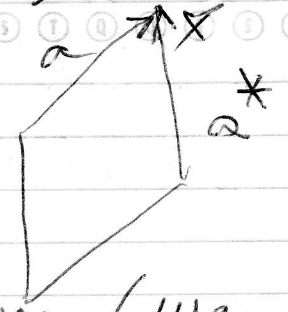
Even though (apesar de) these angles don't affect the volumes of either primal or dual cells, they do affect the volumes of new n-cells, the cells determined by each dual pair. (image)

data 17.04.2020









The area of this parallelogram (user Wolfram Project) does not depend on how a and a^* are attached to each other (they aren't) but only on the angle between them.

↳ important.

(Gauss curvature → space)

↳ angle of Gauss space (179°...)

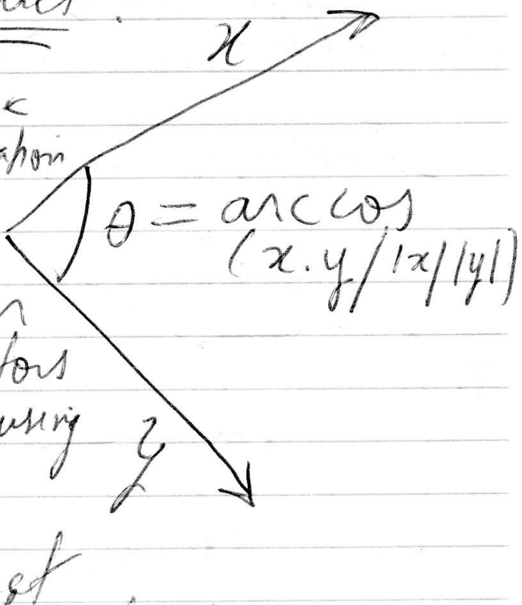
The way we handle (Keidar) angle is, of course, via the inner product:

$\langle a, b \rangle \in R$

is defined for these three cases:

- adjacent $a, b \in K$,
- adjacent $a, b \in K^*$, and now also
- $a \in K$, $a^* \in K^*$.

Geometric interpretation of the angle between two vectors defined using an inner product (of the vectors)



data 17.04.2020

Definition 1.13

A metric (cell) complex of dimension $\underline{\underline{n}}$ is a pair of Hodge-dual cell complexes K an K^* of dimension n equipped with a joint metric tensor, which is a combination of metric tensor for K and K^* as well as inner product of dual pairs:

$$(a, a^*) \to \langle a, a^* \rangle \in \mathbb{R}.$$

IMPORTANT: ✡

Exercise 1.14

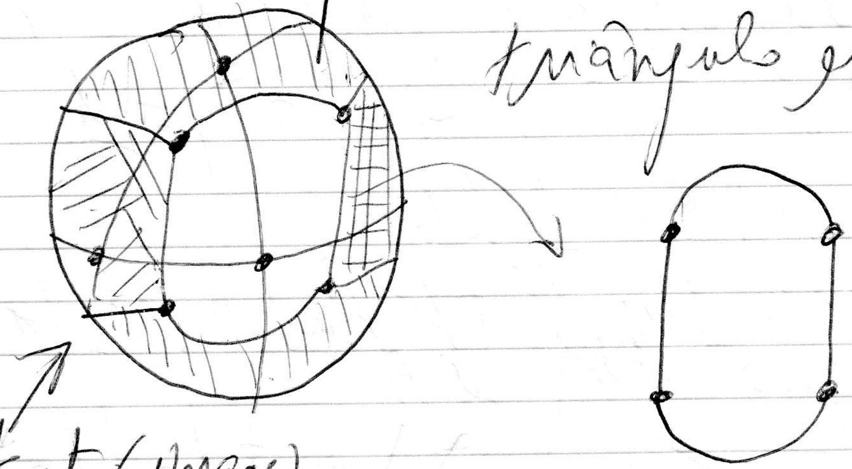
Este cubo inicial será as nossas coordenadas, usando-se coordenadas em funções algébricas

↳ este cubo será transformado em uma esfera dentro

data 17 04 2020

da métrica complexa.

triângulo esférico



Important (image)

Exercise 1.15

Suppose K is a metric complex. Show how the set of its vertices K^0 becomes a metric space.

It follows from the definition that, in addition to the two volume functions of these complexes, we can also derive the angle function.

$(a, a^*) \rightarrow$

$\cos \widehat{a\,a^*} = \dfrac{\langle a, a^* \rangle}{|a|\,|a^*|}$

importantíssimo

A área do paralelogramo depende do ângulo dos lados ou vetores.

The function is well-defined whenever the expression in the right-hand

17.04.2020

belongs to our ring R.

This is always the case when R is a field or $|a| = |a^*| = 1$.

Definition 1.16

We say that K has a rectangular geometry if

$$\langle a, a^* \rangle = \pm |a| |a^*|.$$

In other words, all dual pairs are orthogonal:

$$\cos \widehat{a\, a^*} = \pm 1$$

The case of $n = 1$ previously considered is rectangular.

Definition 1.17

We will say that the complex K has the standard geometry if it is rectangular and also fully normalized:

$|a| = 1$ for all cells $a \in K \sqcup K^*$.

We always assume that $\mathbb{R}^n$ has the standard geometry.

Coordinate Transformations:

data 18 04 2020

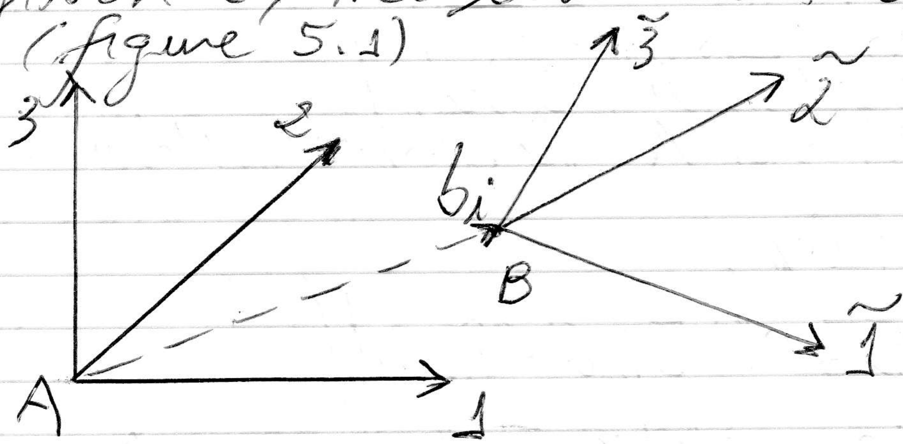
S T Q Q S S D

Definition of Vectors and Tensors

Figure 5.1 Coordinate Transformation

Transformation of Cartesian A into Cartesian System B.

We consider a Cartesian B with coordinate axes ($\tilde{1}, \tilde{2}, \tilde{3}$), representing a point in this system as $\tilde{x}_i$.
The origin of B in terms of the original coordinate system A (1, 2, 3) is given by the coordinates b_j.
(figure 5.1)



Both coordinate system are Cartesian, and the scales in both systems are the same.
The vectors τ^i_m, defined as

$$\tau^i_m = \frac{\partial x_i}{\partial \tilde{x}_m} \qquad i=1,2,3 \quad m=1,2,3$$

are unit vectors tangent to the coordinate directions $\tilde{i}$ (compare (2.5))

data 18.04.2020

S T Q Q S [✓ S] D

with $\tilde{x}_m$ replacing the arc length along the curve, s.

We define similar vectors that are tangent to the coordinates in system A in terms of the coordinates in system B. We call these unit tangent vectors $\overset{m}{\gamma}_i$:

$$\overset{m}{\gamma}_i = \frac{\partial \tilde{x}_m}{\partial x_i}$$

We express the original coordinates of a point x_i in terms of the new coordinates of that same point and vice-versa by integrating the latter two equations:

$$x_i = \overset{i}{\underset{m}{\tau}} \tilde{x}_m + b_i,$$

where b_i represents the origin of B in terms of x_i, and

$$\tilde{x}_m = \overset{m}{\underset{i}{\gamma}} x_1 + \tilde{b}_m,$$

where $\tilde{b}$ represents the origin of the original system A in terms of the new coordinates.

data 18.04.2020

The vectors $\underset{m}{\tau}^{i}$ are mutually*

orthogonal unit vectors,

$$\underset{m}{\tau}^{i}\,\underset{n}{\tau}^{i} = \delta_{mn}.$$

A similar equation holds for unit vectors $\overset{m}{\underset{i}{\gamma}}$,

$$\overset{m}{\underset{i}{\gamma}}\,\overset{n}{\underset{i}{\gamma}} = \delta_{mn}.$$

We obtain a relationship between vectors $\underset{m}{\tau}^{i}$ and $\overset{m}{\underset{i}{\gamma}}$ from (5.1) and (5.2)

$$\underset{m}{\tau}^{i}\,\overset{n}{\underset{i}{\gamma}} = \frac{\partial x_i}{\partial \tilde{x}_m}\,\frac{\partial \tilde{x}_n}{\partial x_i} = \frac{\partial \tilde{x}_n}{\partial \tilde{x}_m} = \delta_{mn}$$

The moduli of $\underset{m}{\tau}^{i}$ and of $\overset{m}{\underset{i}{\gamma}}$ are 1,

we combine this with the latter equation:

$$\underset{m}{\tau}^{i} = \overset{m}{\underset{i}{\gamma}}.$$

We introduce a matrix a_{ij},

data 18.04.2020

8

$$a_{im} = \tau^{i}_{m} = \gamma^{m}_{i} = \frac{\partial x_i}{\partial x_m} = \frac{\partial \tilde{x}_m}{\partial x_i}$$

and write (5.3) and (5.4) as

$$x_i = a_{ij}\tilde{x}_j + b_i,$$

and

$$\tilde{x}_i = a_{ji} x_j + \tilde{b}_i.$$

We observe from (5.9) that

$$a_{im} a_{in} = \frac{\partial x_i}{\partial \tilde{x}_m} \frac{\partial \tilde{x}_n}{\partial x_i} = \delta_{mn},$$

and that

$$a_{im} a_{jm} = \frac{\partial \tilde{x}_m}{\partial x_i} \frac{\partial x_j}{\partial \tilde{x}_m} = \delta_{ij}.$$

Varignon parallelogram

If we consecutively connect the midpoint of any quadrilateral with line segments, we always get a parallelogram.

IMPORTANT: ✡

19.04.2020

Off: Dia de Santo Expedito!!!

IMPORTANT:

Esta propriedade é um dos instrumentos que eu deverei usar para a checagem dos cálculos.

Use-o conjuntamente com os demais descritos no

item 144 (20200417),

subitem B4 (B4) e

The Trisectors by Dudley

subitem C (Feuerbach's theorem)

↳ que faz referência ao

item 138 (20200416).

Vou explicar melhor:

Com Varignon Parallelogram poderemos obter um paralelogramo, ou seja 2 pares de retas paralelas que foram obtidas de um quadrilátero (que nem sempre) é irregular.

Desta forma nós conseguiremos obter padrões para realizar deduções de cálculos de áreas e assim,

data 19.04.2020

inferimos a área total deste quadrilátero irregular, cujas (~~arestas~~) lados não são paralelas e os ângulos formados entre elas (~~arestas~~) (lados) são desconhecidos.

Obs: Aresta é a reta que se origina a partir da intersecção de 2 planos que formam um ângulo.
(3D do quadrilátero irregular)

Varignon parallelogram aplica-se para todos tipos de quadrilátero: regular e irregular.

(quadrado)
- ↳ é um paralelograma.
- ↳ é um polígono que reúne as características do losango e do retângulo ao mesmo tempo.
- ↳ os lados são congruentes (mesma medida).
- ↳ um quadrado também pode ser chamado de losango.

Obs: 1. Todo paralelogramo é quadrado, retângulo ou losango;
2. Todo retângulo ou losango é também um quadrado.

IMPORTANT:

Varignon parallelogram

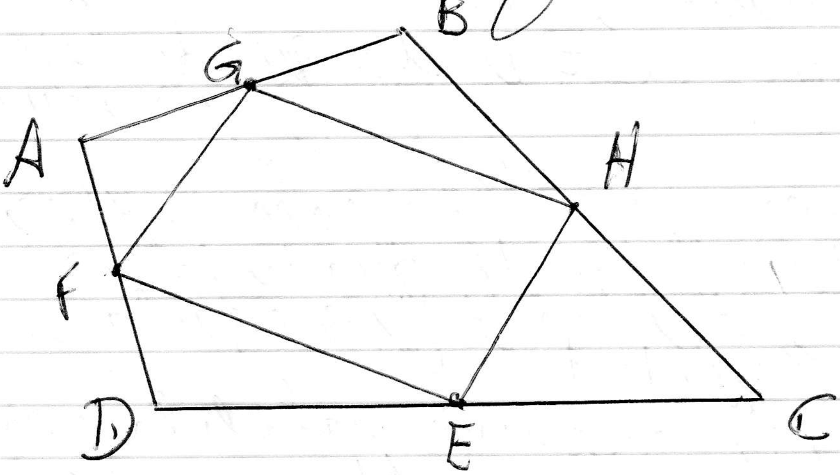
data 19.04.2020

8

VARIGNON PARALLELOGRAM

has half the area of the original quadrilateral.

(mais um instrumental para calcular a área de um determinado quadrilátero).



The area of parallelogram EFGH is one-half of a area of quadrilateral ABCD, and the perimeter of paralllogram EFGH equals AC + BD.

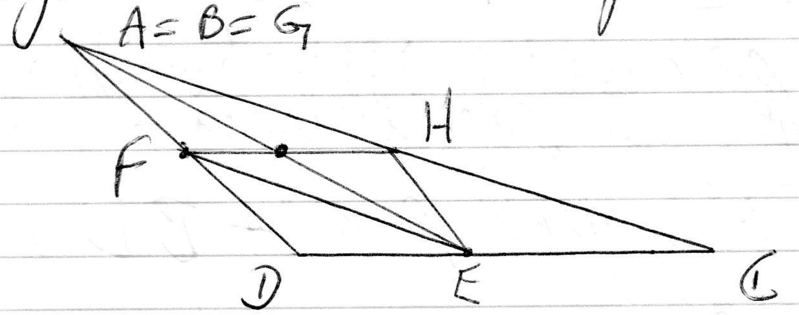
IMPORTANT:

Outro instrumento para checagem dos meus calculos.

Quantas mais redundâncias de checagem e melhor, diminui o erro.

data 19 04 2020
X

Figure 4.17 (Important)



If we reduce the length of one side of the quadrilateral, AB to length zero. (We get a triangle with one vertex having points A, B, and G coincide as in figure 4.17.
Here, too, the resulting

Varignon Parallelogram

still exists and it (is) one-half the area of the original triangle (or quadrilateral with a zero-length side).

Relate with Figure 4.14 where we found that the triangle ABC was partitioned into four triangles of equal area, leaving us with a similar result when we consider the parallelogram ADFE in figure 4.14 which is analogous to parallelogram AFEH in Figure 4.17.

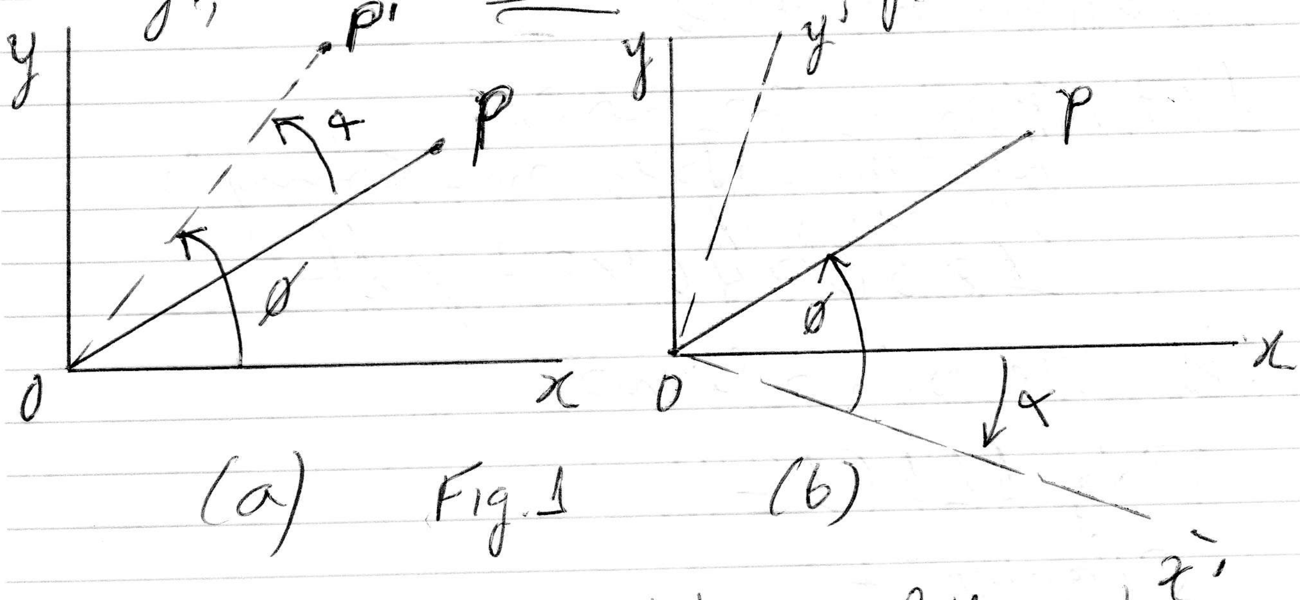
Angular Momentum Brink/
Angular_momentum_1968.pdf
Pág. 05(13)

The geometrical symmetry
operations of translation and

19.04.2020

rotation can be looked at in two ways, called active and passive.



(a) Fig. 1 (b)

a) Represents a rotation of the system. A vector OP is carried into OP' by the rotation.

b) Represents the equivalent
rotation of axes.

The vector OP remains fixed, but its coordinates are changed. The position of OP relative to the new axes in (b) is the same as that OP' relative to axes in (a).

A rotation actually rotates the system from one position to another. The passive approach interprets the symmetry operations as coordinates transformations and the symmetry of the dynamical laws is expressed by

data 19.04.2020

stating that the equations of motion are invariant under translation or rotation of axes. —

7.2. the Length of a Contour.

Polygon:

Condition:

$\gamma : [a,b] \to \mathbb{C}$ is given smooth path.

We can consider an inscribed polygon as an approximation to the path and its length will be an approximation to the length of the path.

polygon $\Rightarrow$ vertices $\{z_0, z_1, \ldots, z_n\}$.

data 19.04.2020

X

Then the length of such (de tal) a polygon path is the SUM of the lengths of its straight line segments, namely,

$$\sum_{j=1}^{n} |z_j - z_{j-1}|.$$

Suppose that the ends of the line segments correspond to values $t_0, t_1, \dots, t_n$ of the parameter, that is, $z_j = \gamma(t_j)$.

Then

$$\sum_{j=1}^{n} |z_j - z_{j-1}| = \sum_{j=1}^{n} |\gamma(t_j) - \gamma(t_{j-1})| =$$

$$\sum_{j=1}^{n} \left| \frac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}} \right| (t_j - t_{j-1}),$$

with $a = t_0 < t_1 < \dots < t_n = b$.

Now, the quotient $\dfrac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}}$

can be considered an approximation to the derivative $\gamma'(t_j)$,

in which case the sum of the right hand side (lado direito) becomes an approximation to an integral.

data 19.04.2020

S T Q Q S S [✓ D]

$$\sum_{j=1}^{n} \left| \frac{\gamma(t_j)-\gamma(t_{j-1})}{t_j-t_{j-1}} \right| (t_j-t_{j-1})$$

$$\xrightarrow{\text{approx}} \int_a^b |\gamma'(t)|\,dt.$$

Indeed (de fato), in view of the assumed smoothness of γ one might expect that the left hand side converges to the right hand side as $\max_j (t_j - t_{j-1}) \to 0$.

Rather than (ao invés de) prove this here, we will just take this as motivation for our definition of the length of a path, as follows.

1.6 The Riemann Sphere and the Extended Complex Plane.

Let S^2 denote the sphere →

data 19 04 2020

$\{(x,y,z)\in\mathbb{R}^3 : x^2+y^2+z^2=1\}$ in $\mathbb{R}^3$ and let N denote the point (0,0,1), the "north pole" of S^2.

Think of $\mathbb{C}$ as the plane $\{(x,y,z) : z=0\}$, containing the equator of S^2.

Then given any point P in the plane, the straight line through P and N meets the sphere S^2 in a unique place, P' say. As P varies over the plane, the corresponding point P' varies over $S^2\setminus\{N\}$.

This sets up a one-one correspondence between $\mathbb{C}$ and $S^2\setminus\{N\}$.

Pag. 222(233) Chapter X

Two-Variable Iwasawa Theory of Elliptic Curves.

159) 20200502

A) "A line is considered a circle with infinite radius and zero curvature".

"In fact the work was of such quality that Weingarten received a prize for work on the lines of curvature of a surface in 1857".

"A formula for the line integral of the geodesic curvature along a closed curve is known as the Gauss Bonnet theorem".

"That is, in this case, the Riemann curvature tensor has 4x4x4x4=256 components!"

data 02.05.2020

S T Q Q S S D

"A deeper characterization of a helix is that is the unique curve in 3-space for which the ratio of curvature to torsion is a constant, a result know as Lancret's theorem."

"Some of his work on physical topics relates to his non-Euclidean geometry for he examined how the gravitational potential as given by Newton would have to be modified in a space of negative curvature".

"The local curvature could then be computed from the coefficients of this quadratic surface".

"He showed that spaces of constant curvature could have several different topological structures".

"Surfaces of constant mean curvature or constant Gaussian curvature are now called Weingarten surfaces"

(surfaces)

"The value assigned for each cell is the value of Gaussian curvature at the cell centroid"

(centroid).

02 05 2020

"Gaussian curvature is positive for surfaces like a hemisphere, which are either concave or convex in all the directions"

A Treatise on Solid Geometry.pdf

Pag. 67(97)

104. To find the distance between two points whose (de quem) equations are given

105. (Pag. 69(99))

We deduce the expression for the square of the distance.

106. (Pag. 69(99)) IMPORTANT:

data 02.05.2020

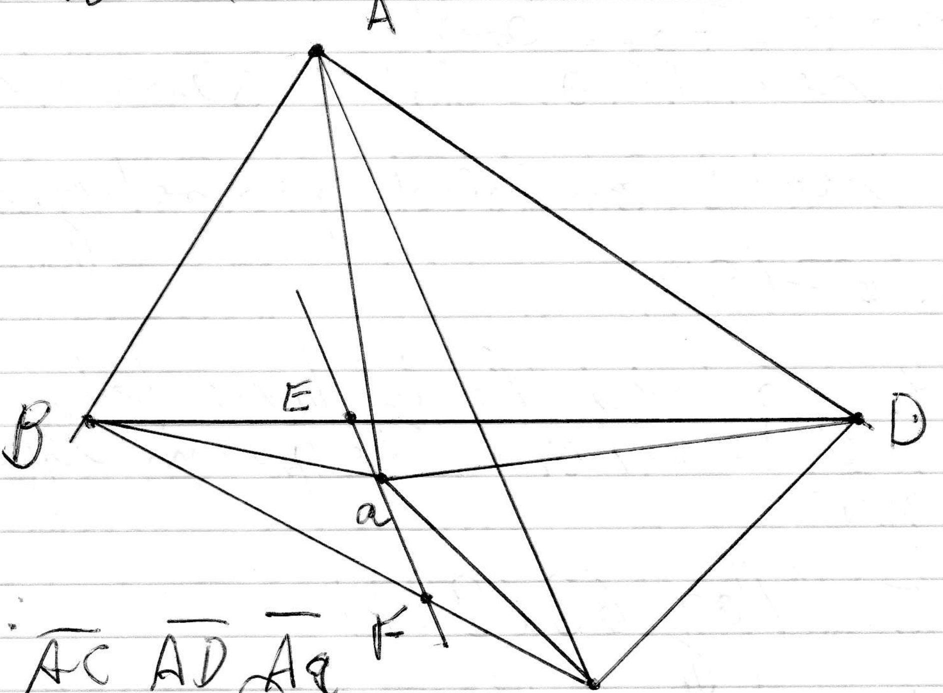
106. To find the relation between the co-ordinates of a plane

→ usar para triangular um ponto que foi projetado da superfície curvada para o plano (superfície plana).

IMPORTANT:

O ponto A é o referencial inicial para a projeção em uma superfície.

O ponto A pode estar sobre a curvatura.



Obs: $\overline{AB}$ $\overline{AC}$ $\overline{AD}$ $\overline{Aa}$ são projeções a partir do ponto A para a superfície triangular $\triangle BCD$.

02.05.2020

Pág. 70 (100) Nota de rodapé

* The equation of a straight line, referred to trilinear co-ordinates,) is

$$\alpha \frac{\varpi_1}{p_1} + \beta \frac{\varpi_2}{p_2} + \gamma \frac{\varpi_3}{p_3} = 0,$$

where

$\varpi_1, \varpi_2, \varpi_3$ are the perpendiculars, estimated in the same direction, from the angular points of the fundamental triangle upon (em cima de) the straight line, and

p_1, p_2, p_3 those upon the sides.

Now taking EF for the straight line, and BCD for the fundamental triangle, for a, a point in that line,

$$\frac{\alpha}{p_1} : \frac{\beta}{p_2} : \frac{\gamma}{p_3} :: aCD : aDB : aBC,$$

$$\therefore \varpi_1 . aCD + \varpi_2 . aDB + \varpi_3 . aBC = 0,$$

whence (de onde) the equation in the text.

data 02 05 2020

Pag. 203(215) Chapter 14

Adventure in thought
Albert Einstein

Pag. 208(220)

Doctrine of Space and Time

data 05.05.2020

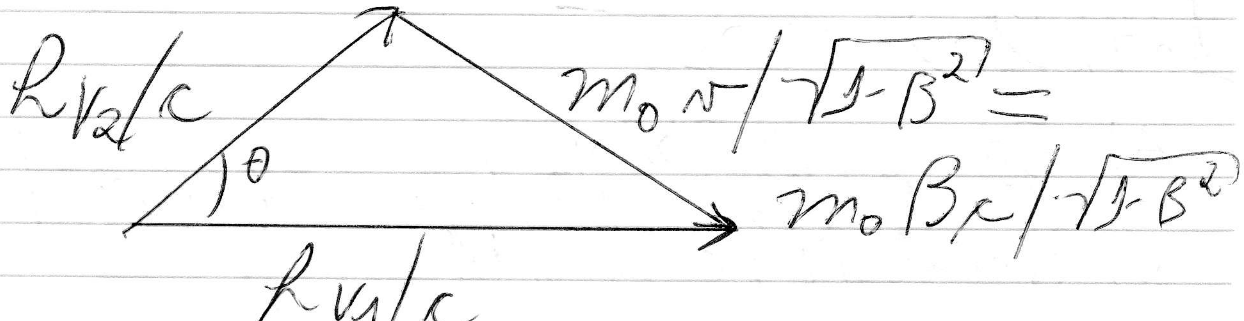
Pag.209) Whereas Lorentz had struggled to explain the invariance of the speed of light with a constructive theory that hypothezid motion-dependent molecular forces, Einstein bypassed all the complications by simply promoting the constancy to a postulate.

For Lorentz and his contemporaries, it was a problem, for Einstein a principle.

A2) The Quantum Physicists And an Introduction to their Physics (1970) in pdf.

Pag. 30(43)

Conservation of momentum



Conservation of momentum requires that the incident photon vector be equal to the vectors representing the scattered photon and the recoil electron:

and this (with the law of cosines)

05 05 2020

leads to the equation:

$$(m_0\beta c/\sqrt{1-\beta^2})^2 =$$
$$(h\nu_1/c)^2 + (h\nu_2/c)^2 - 2(h\nu_1/c)(h\nu_2/c)\cos\theta$$

Obs:
That $h\nu/c$ is a measure of photon momentum can be seen by the equation two Einstein equations for total energy,
$E = h\nu$ and $E = mc^2$: $h\nu = mc^2$.

Pág. 196(214) Integer 67

An Inequality on $\pi(x)$

It is not known whether or not

$$\pi(x+y) \leq \pi(x) + \pi(y)$$

for all sufficiently large x, y.

06.05.2020

Extending work of Rosser and Schoenfeld, various authors have proved related results.

Krawczyk proved the following,

$\pi(kx) < k\pi(x)$ for

$k \geq e$, $x \geq 67$.

For $\epsilon > 0$, $x \geq 17$, $y \geq 17$,

$x + y \geq 1 + e^{4(1+1/\epsilon)}$, it has been shown that

$\pi(x+y) < (1+\epsilon)(\pi(x) + \pi(y))$.

There is an interesting connection between Conjecture A ($\pi(x+y) \leq \pi(x) + \pi(y)$, $x, y \geq 2$) and the generalization of the twin prime conjecture that follows it.

Pág. 163(211) Chapter 14 Surface theory

06 05 2020

In the spring of 1816 Gauss had proposed as a prize problem for a new astronomical journal founded by von Lindenau and Bohnenberg (Bohnenberger), the projecting of two curved surfaces on each other, yet preserving similarity in the smallest parts.

At the time he had the solution and had thought out a projection by means of parallel normals on the sphere of radius unity.

In his concept the development or bending of curved surfaces was a special case of projection.

(resolveu)
At this time he had worked out the concept of the total curvature of a portion of a surface, and the concept of the measure of curvature at one point of a surface, as well as preservation of the measure of curvature in spite of bendings.

In the time from 1812 to 1816 he was busy with the theory of the shortest lines on the elliptic spheroid, and conceived of the cartesian coordinates of a point of a curved surface as functions (eixos curvos) of two auxiliary magnitudes.

167) 20200507

Deus é oniexistente (eterno),
onipotente
onisciente
onipresente.

O Universo é parte de Deus
e portanto, o Universo sempre existiu.

O Big Bang é um momento ativo do Universo.

O Universo é ativo em decorrência dos Forças Fundamentais de Interação

Weak
Strong
Electromagnetic

A gravidade não é uma força fundamental, mas é decorrência da interação das 3 forças fundamentais do Universo.

data 07.05.2020

Gravitation is by far weakest* of the three interactions at atomic scale, where electromagnetic interactions dominate.

Albert Einstein não conseguiu fazer a unificação dos forças fundamentais pois considerou a gravidade como uma força fundamental e não uma consequência dos 3 forças fundamentais de interação do Universo.

General relativity generalizes special relativity and refines Newton's law of universal gravitation

↳ descreveu o efeito das 3 forças fundamentais do Universo e não uma força em si mesma (independente), mas decorrentes daquelas.

providing a unified description of gravity as a geometric property of space and time (spacetime).

In particular the curvature of spacetime is directly related to the energy and momentum of whatever (tanto faz) matter and radiation are present.

Light Cone:

Geometric Newton → classical mechanics is a limiting case of special relativity

data 07.05.2020
8

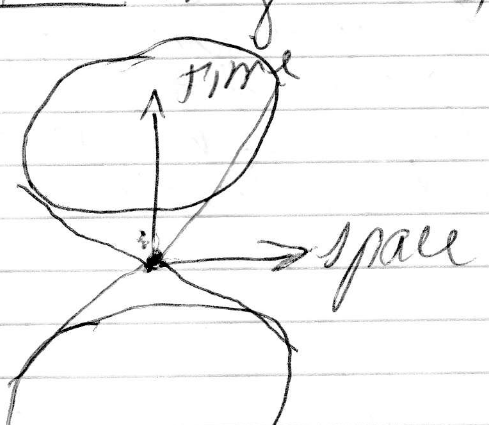
mechanics. In the language of symmetry, where gravity can be neglected, physics is Lorentz invariant (Hendrik Lorentz) as in special relativity rather than Galilei invariant as in classical mechanics.

The defining symmetry of special relativity ~~th~~ is the Poincaré group, which includes translations, rotations and boosts.

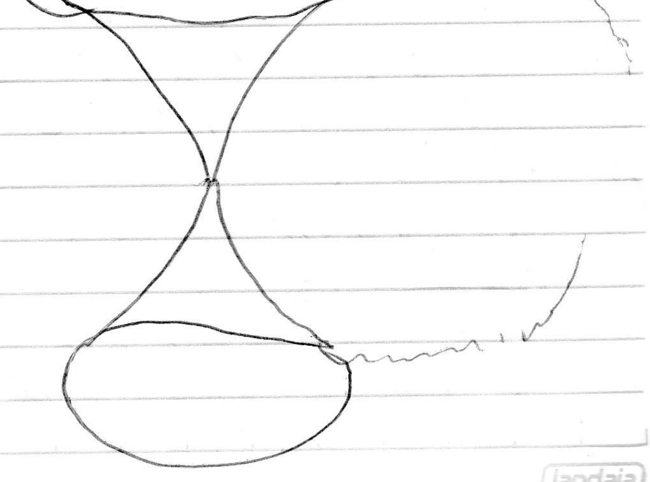
The differences between the two become significant when dealing with speeds approaching the speed of light and with high-energy phenomena.

A velocidade da luz é definida como uma constante universal, mas esta não absolutamente constante, pois a sua velocidade depende do meio em que trafega e com base nas 3 leis fundamentais de interação, aplicáveis a curvatura do espaço-tempo.

Voltando (Light cone)



Meu: light cone



07 05 2020

With Lorentz symmetry additional* structures are defined by the set of light cone. These sets are observer-independent.

In conjunction with the world lines of freely falling particles, the light-cones can be used to reconstruct the

space-time's semi-Riemannian metric,

at least up to a positive scalar factor.

In mathematical terms, this defines a conformal structure or conformal geometry.

↳ the conformal isometries of a domain therefore (portanto) consist of holomorphic self-maps. In particular, on the conformal compactification – the Riemann Sphere – the conformal transformation are given by the Möbius transformations

↳ can be visualized as the complex number plane wrapped around a sphere (by some form of stereographic projection).

Important:

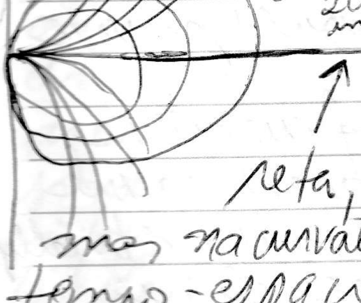
Stereographic projection is conformal, meaning that it preserves the angles at which curves across each other. Stereographic projection does not preserve area. In general, the area of a region of sphere does not equal the area of its projection onto the plane.

$$z \rightarrow \frac{az+b}{cz+d}$$

where $ad-bc$ is nonzero.

(o meu é em 3D)

2 cone invertido



reta, mas na curvatura tempo-espaço não há [illegible] reta perpendicular ao plano em que houve a transformação.

data 07.05.2020

$dA = \frac{4}{(1+X^2+Y^2)^2} dX dY$. Along the unit circle $X^2+Y^2=1$, there is no inflation of area in the limit, giving a scale factor of 1. Near (0,0) areas are inflated by a factor of 4, and near infinity areas are inflated by arbitrarily small factors. The metric space is given in (X,Y) coordinates by $\frac{4}{(1+X^2+Y^2)^2}(dX^2+dY^2)$, and is the unique formula found in Bernhard Riemann's Habilitationsschrift on the foundations of geometry, delivered at Göttingen in 1854, and entitled

Über die Hypothesen welche der Geometrie zu Grunde liegen.

Copy: ARQ_BASICS_04/DEUS/Geom.pdf

Source: www.maths.tcd.ie/pub/HistMath/People/Riemann/Geom/Geom.pdf.

Source: https://www.emis.de/classics/Riemann/

→ The Mathematical Papers of Georg Friedrich Bernhard Riemann.

No map from the sphere to the plane can be both conformal and area-preserving. If it were, then it would be a local isometry and would preserve Gaussian curvature.

→ is an intrinsic measure of curvature, depending only on distances that are measured on the surface, not on the way it is isometrically embedded in Euclidean space. This is content of the Theorema egregium (1827).

g) Palais_FundamentalTheorem.pdf

Total Curvature (Gaussian Curvature) The surface integral of the Gaussian curvature over some region of a surface is called the total curvature. The total curvature of a geodesic triangle equals the deviation of the sum of its angles from π. The sum of the angles of a triangle on a surface of positive curvature will exceed π, while the sum of the angles of a triangle on a surface of negative curvature will be less than π. On a surface of zero curvature, such as the Euclidean plane, the angles will sum to precisely π radians. $\sum_{i=1}^{3} \theta_i = \pi + \iint_T K \, dA$

Obs. Gauss-Bonnet theorem

cont. ... Gaussian curvature. The sphere and the plane have different Gaussian curvatures, so this is impossible.

Circles on the sphere that do not pass through the point of projection are projected to circles on the plane. Circles on the sphere that do not pass through the point of projection are projected to straight lines on the plane. These lines are sometimes thought of as circles through the point at infinity, or circles of infinite radius. All lines in the plane, when transformed to circles on the sphere by the inverse of stereographic projection, meet at the projection point. Parallel lines, which do not intersect in the plane, are transformed to circles tangent at projection point. Intersecting lines are transformed to circles that

data 07.05.2020

intersect transversally at two points in the sphere, one of which is the projection point.

Cross Section: A graph of $z=x^2+xy+y^2$. For the partial derivative at (1,1,3) that leaves y constant, the corresponding tangent line is parallel to the xz plane. Observamos uma curvatura da superfície, compare esta curvatura com as equações dA da Stereographic Projection. ✡.

dentro do losângulo

Neste diagrama, devemos observar que o ponto inicial de referência deverá ser alterado para o ponto inicial do Big Bang, ou seja, para o momento em que ocorreu o Big Bang mas havendo a alteração do modelo utilizado para o desenvolvimento do Universo.

As 3 forças fundamentais de interação do Universo geram como efeito a gravidade, como uma consequência "sine qua non" da curvatura do Universo, gerada em decorrência destas 3 forças fundamentais universais e não em decorrência direta da gravidade, mas indiretamente.

data 07 05 2020

Speed of light: In 1865, James Clerk Maxwell proposed that light was an electromagnetic wave, and therefore travelled at the speed c appearing in his theory of electromagnetism. In 1905, Albert Einstein postulated that the speed of light c with respect to any inertial frame is a constant and is independent of the motion of the light source. c = celeritas

✡ In 1856, Wilhelm Eduard Weber and Rudolf Kohlrausch had used c for a different constant later shown to equal $\sqrt{2}$ times the speed of light in vacuum.

Poincaré group: first defined by Hermann Minkowski (1908) as the group of Minkowski spacetime isometries

↳ ignoring the effects of gravity (i.e)

Minkowski Space → the presence of gravity spacetime is described by a curved 4-dimensional manifold for which the tangent space to any point is a 4-dimensional Minkowski space. Thus, the structure of Minkowski space is still essential in the description of general relativity.

Hyperbolic stereographic projection

Red circular arc is geodesic in Poincaré disk model; it projects to the brown geodesic on the green hyperboloid.

Curvature: Gaussian Curvature

Formally, Gaussian curvature only depends on the Riemann metric of the surface. This is Gauss's celebrated Theorema Egregium, which he found while concerned with geographic surveys and mapmaking.

Gaussian curvature K at the point P can be computed by the Bertrand–Diguet–Puiseux Theorem as

$$K = \lim_{r \to 0^+} 3 \left(\frac{2\pi r - C(r)}{\pi r^3} \right)$$

jasonpadgett.info

Jason became fascinated with
number Pi, irrational number
that is

"a fundamental building block
of everything around me,
a signifier of nature's
perfect symmetry".

Struck by Genius

A geometria do pi é tecida no espaço-tempo
Sempre achei que a geometria
de Pi desenha anéis Einstein
(também conhecidos como
lentes gravitacionais).

The geometry of Pi

A geometria do pi é tecida no
espaço-tempo e é impressionantemente
bonita e é encontrada às vezes em
lugares surpreendentes.

Sempre achei que a geometria
de Pi desenha anéis Einstein. (também
conhecidos como lentes gravitacionais),
mas parece estar relacionado com estes
novos objetos também.

The geometry of Pi is woven into spacetime and is stunningly beautiful and it is found sometimes in surprising places.

I've always thought the geometry of Pi described Einstein rings (aka gravitational lensing), but it seems to be related to these new objects also.

Pág. 168(182)

5.4 KAM theory

continue fraction

...

A quadratic irrational is the solution to a quadratic equation with integer coefficients and has periodic continued fractions, such as

$$\sqrt{2} = [1; 2, 2, 2, \dots] \quad (5.24)$$

Nonquadratic irrational have nonrepeating continued fractions, such as

$$\pi = [3; 7, 15, 1, 292, 1, 1, 1, 2, 1, 3, 1, 14, 2, 1, 1, 2, 2, 2, 2, 1, 84, 2, \dots] \quad (5.25)$$

$$\pi - 3 \approx [0; 7, 15, 1, 0, 0, 0, \dots]$$

$$= \cfrac{1}{7 + \cfrac{1}{15 + \cfrac{1}{1}}} = 0{,}14160 = \frac{177}{1250} \quad (5.26)$$

David G. Blair - The Detection of Gravitational Waves (2005).pdf
Pag. 6(31)

fractionally larger than π.

John Wheeler introduced the slogan "matter tells space how to curve, space tells matter how to move" to describe general relativity.

This hides the complexity
because in reality:
matter, the motion of matter,
and radiation density,
including propagating
waves of curvature
tell spacetime how to
curve.

Curvature creates curvature,
and influences its propagation!

the curvature...pdf/

obs: surface in R^3

As sometimes occurs, one of the most intriguing unresolved problems involving Gaussian curvature is also one of the easiest to understand.

Let $z = u(x, y)$ be a surface in $\mathbb{R}^3$.
Its Gaussian curvature
$K(x, y)$ is given by the formula

$$\frac{u_{xx}\, u_{yy} - u_{xy}^2}{(1 + |\nabla u|^2)^2} = K(x, y).$$

Tigger Wodds (golfista)

eu tive uma premonição deste jogador. Nesta manhã, veio em minha mente da vida conturbada deste atleta e no período da tarde, saiu na televisão que o mesmo sofreu um acidente de trânsito na Califórnia

Nem sabia o nome dele mas lembrava o que tinha acontecido durante o seu passado turbulento e sem esperar, vi o noticiário, fiquei surpreso

Para mim, tudo já está escrito e o nosso poder de decisão, livre-arbítrio, é muito limitado. Algumas coisas marcantes em nossas vidas tem que acontecer porque já está escrito por Deus. Deus não deseja o nosso mal, os fatos acontecem quando as pessoas se afastam do verdadeiro caminho de Deus, ou seja acontece àqueles que se afastam da verdade.

Hyperbolic Manifolds An Introduction
(Albert Marden) in 2 and 3D

Condritos carbonáceos

6 nº que definem tudo o universo

1. matéria bariônica
2. matéria escura
3. energia escura
4. profundidade óptica
   (mais astrofísico de todos os parâmetros do modelo padrão da cosmologia)

✱ Para determinar a profundidade óptica do universo é feita uma medição da polarização da CMB

CMB – radiação cósmica de fundo em micro-ondas.

Polarização
intensidade
comprimento de onda } 3 características de uma onda de luz.

5. } flutuações quânticas
6. } (diminutas)

Chamado de espectro de potência primordial e descreve as flutuações na densidade do Universo no espaço tridimensional.

Parâmetros restante, chamado índice espectral escalar.

As pequenas variações de energia que estavam presentes no Universo primitivo, dependem da escala angular.

O ruído cósmico primordial é ligeiramente rosado.

Universo: 13,8 bilhões de anos
(40 milhões de anos variação ±)

A observação mais restritiva é a da anisotropia da CMB: as diminutas flutuações da temperatura.

$360 \div 13 = 27{,}\overline{692307}$

$360 \div 11 = 32{,}\overline{72}$

$\boxed{360 \div 15 = 24}$ hours

$360 \div 16 = 22{,}5$

Vocês estão querendo construir um túnel para o futuro usando uma colher de chá! Vocês estão equivocados, vocês devem usar a dinamite. Vocês devem implodir a forma como fazem matemática, física, química etc.

David de Michelangelo foi construído com uma colher de chá!

Precisamos ir além e unir a colher de chá e a dinamite.

A constante de expansão do Universo (Hubble) está sendo calculada de forma imprecisa pois vocês estão usando conceitos e cálculos ultrapassados. É chegada a hora de quebrarmos os grilhões que nos prendem ao passado como uma bola de ferro presa aos nossos pés. Para voar precisamos deixar o chão que achamos ser seguro e que muitas vezes poderá se abrir bem embaixo dos nossos pés.

Die Vermessung der Welt
(Gauss)
Medindo o Mundo

Berhard Rieman

David Hilbert – queria lançar o plano de reconstruir os fundamentos da matemática, para torná-los consistentes e livres de paradoxos.

Gödel, com sua tese de doutorado, pôs um ponto final a essa pretensão, demonstrando que havia problemas na matemática que eram impossíveis de serem resolvidos.

A deslumbrante clareza e exatidão da matemática era, na realidade, um labirinto repleto de paradoxos.

Gödel provou: 1) Em um sistema formal axiomático consistente que possa expressar fatos sobre aritmética básica, há enunciados verdadeiros que não podem ser provados; 2) Que a consistência do sistema não pode ser provada dentro do mesmo sistema. São os teoremas da incompletude.

Zero:

Fortaleza de Gwalior na Índia Central.
(registro mais antigo do zero)

Índia – Shunya
(a idéia filosófica do vazio para representar o novo termo matemático).

“Porque a sabedoria serve de defesa,
do mesmo modo que o dinheiro!
Eclesiastes 7.12

Quem toma emprestado é escravo
de quem empresta.
Provérbios 22.7

"Vocês foram comprados por
alto preço;
não se tornem escravos de
homens."
1 Coríntios 7:23

"Tudo tem o seu tempo determinado,
e há tempo para todo o propósito
debaixo do céu."
Eclesiastes 3:1

7 Segredos da Prosperidade Judaica:

1) Ser perito Provérbios 22:29
faça, seja o melhor.
2) Tem uma cultura empreendedora.
"Ninguém fará por você aquilo
que deve ser feito por você."
3) Ter mentores
"Quando não há conselhos os planos
se dispersam,
mas havendo muitos conselheiros
eles se firmam."
Provérbios 15:22
4) Aceitar a repreensão
"Pobreza e afronta virão ao
que rejeita a instrução, mas o
que guarda a repreensão será
honrado".
Provérbios 13:18

4) Cont.

"Melhor é a repreensão franca do
que o amor encoberto"
Provérbios 27:5

"Todo o que ama a disciplina
ama o conhecimento,
mas aquele que odeia a repreensão
é tolo"
Provérbios 12:1

"Quem acolhe a disciplina
mostra o caminho da vida,
mas quem ignora a repreensão
desencaminha outros"
Provérbios 10:17

5) Ter um bom nome

"Vale mais ter um bom nome
do que muitas riquezas;
e o ser estimado é melhor
do que a riqueza e o ouro"
Provérbios 22:1

→ Boa reputação.

6) Guardar dinheiro

"Há tesouro precioso e azeite na
casa do sábio, mas o homem insensato
os devora" Provérbios 21:20

7) Ter união:

"Como é bom e agradável
quando os irmãos convivem
em união!"
Salmos 133:1

Quark bottom

O modelo padrão não pode explicar a natureza da gravidade.

quarks bottom devem decair em números iguais de partículos de elétrons e muons (uma partícula elementar semelhante ao elétrons)

Na realidade, produz mais elétrons do que múons.

Partícula ainda não descoberta → leptoquark

Padrão ouro → nível chamado
cinco sigma
(1/3,5 milhões)

Acelerador é três sigma – 1/1000.

—

"A descoberta de uma nova força na natureza é o santo graal da física de partículas".

off:

X17 → 5ª força da natureza?

Decaimento do elétron (conflito)

↳ Hélio

As partículas do átomo foram divididas em ângulos de 115 graus, muito mais do que o esperado.

No momento que O átomo decai, o excesso de de energia produzidos criou brevemente uma nova partícula desconhecida, que se decompõe rapidamente em pósitron e elétron.

33X mais massa que um elétron

= 17 megaeletronvolts.

Este decaimento também aconteceu com o berílio-8

Berílio

No berílio o ângulo foi 140 graus

Obs: À medida que a energia da luz produzida pelo berílio aumenta quando libera um elétron e um pósitron, o ângulo entre os dois deve diminuir.
Mas não foi o que aconteceu no experimento de 2016.

Pode ser um elo entre o mundo visível e a matéria escura.

Projective isotomic conjugation

Import

Pág. 112(129)

There are several kinds of conjugate maps (isogonal, isotomic) with respect to fixed triangle, defined as colineations over E_2^* for example by means of point multiplication [6].

The theorems of Ceva and Menelaus give rise.

Definition 1.2.

Projective ($\mathbb{R}P_2$) – isotomic conjugation with respect to basic
P_2
ΔABC is the map

Pág. 120(137)

Canonical commutation relation
↳ canonical conjugate quantities

Conjugate variables are pairs of variables mathematically defined in such a way that they become Fourier transform duals, or more generally are related throught Pontryagin duality. The duality relations lead naturally to an uncertainty relation (Heisenberg uncertain).

Source: Pag. 120 (137)

(Heisenberg relations in the general case.)

↪ canonical conjugate

Lei de Leavitt → relação
período - luminosidade.

qto mais brilhante a magnitude, mais longo o período.

Em 2008 → membros da comunidade astronômica votaram pela mudança do nome do que antes era chamado de relação período-luminosidade para Lei de Leavitt.

---

vontade de Deus
+
liberdade do homem.

O homem morre pelo mau uso da liberdade do homem.

A maioria das pessoas morrem pelo mau uso da liberdade do homem e não por vontade de Deus, mas quando chega a hora é a vontade de Deus?

Cor Azul → radiação Tcherenkov

20210515

Eletromagnetismo (responsável pela luz, eletricidade, ímãs)

A força nuclear forte (responsável por manter tudo unido)

A força nuclear fraca (responsável pela radiatividade)

Para cada força existe uma ~~fo~~ partícula intermediadora.

Fótons são as partículas intermediadoras das forças eletromagnéticas.

gluons → força forte

Bósons pesados → força fraca.

Blocos de construção da matéria são formados pelas duas categorias:
bósons
férmions

Toda a matéria → 3 férmions:
2 Quarks
1 elétron.

2 tipos de Quarks no modelo padrão →

mas apenas 2 deles – os mais leves – formam prótons e nêutrons

Off: Quarks beleza (decaimento) geram múons ou elétrons (produzindo ambos em quantidades iguais).

Mas experimentos começam a provar algo diferente.

Não se sabe se é por causa de:

a/ uma nova partícula ou

b/ nova força fundamental.

Quarks beleza < múons

> elétrons

↑

decaiam com menos ou mais frequência.

5 Forças fundamentais: eletromagnetismo
gravidade
força nuclear forte
força nuclear fraca
força de Higgs.

1 Higgs pesa ≅ átomo de iodo
↳ não tem spin.

As outras partículas ~~Não~~ têm spin mas tem um giro intrínseco.

obs: Higgs não tem giro ou spin.

Higgs → composição (vários partículas fund)
ou
supersimetria

(solução para entender o Higgs).

píon → partícula sem spin
→ prótons
nêutrons

toda a partícula tem um par.

—

Universo tem dois tipos de partículas
{ matéria → { quarks → P N
{ léptons
{ força → { elétron
{ neutrino

—

Quark decai em proporções diferentes
Para cada 100 decaimentos com elétrons houve 85 decaimentos com múons.
(
→ Quebra da simetria cósmica

eletrodinâmica quântica

Campo magnético intrínseco é medido em unidades típicas para partículas elementares.

$(g)\_\{\text{experimental}\} = 2.00115965218073$

$(g)\_\{\text{teórica}\} = 2.00115965218178$

Efeito Schwinger

Um dos motivos é a analogia do eletromagnetismo com a gravidade.

Na vizinhança de um buraco negro pares de partículas são geradas para neutralizar o forte campo gravitacional do buraco negro

Bloch, Kato, Selmer, Frey,

Fermat.

Kepler odiava dar aulas
e uma das suas paixões era
a Geometria, que lhe dizia existir
antes da Criação.

Kepler foi ser assistente de
Tycho Brahe (Praga)

3ª Lei Kepler:

"Os quadrados dos períodos
de translação dos planetas são
proporcionais aos cubos dos
semi-eixos maiores de suas
órbitas".

Kepler quase descobriu a Lei da
Gravidade, mas manteve a
força com o nome de
"magnetismo".

Kepler - 1571 - 1630
Newton - 1643 - 1727

Kepler na ótica determinou que a
intensidade de uma onda de luz diminui
com o quadrado da distância.
Também na neurofisiologia e foi
o primeiro a descobrir que as imagens
no olho humano são projetadas na
retina de cabeça para baixo.

gauntlet = manopla.

A Cornucopia of Quadrilaterals - MAA Press - Vol 45

The midpoints of the sides of any quadrilateral are the vertices of ~~a~~ parallelogram, or that in a convex quadrilateral (not a parallelogram) the line through the mid points of the diagonals (the Newton line) is equidistant from opposite vertices, or that, if your quadrilateral has an inscribed circle its center lies (encontra-se) on the Newton line.

There are results dating back to Euclid: the side-lengths of a pentagon, a hexagon, and a decagon inscribed in a circle can be assembled into a right triangle (the proof uses a quadrilateral and circumscribing circle); and results dating to Erdős: from any point in a triangle the sum of the distances to the vertices is at least twice as large as the sum of the distances to the sides.

teoria do espaço-tempo modular

A gravidade deixa de ser uma força de atração entre dois corpos e passa a ser uma deformação no espaço-tempo causada pela matéria, de acordo com a sua massa.

Gravidade Quântica de Loop (LQD), que sugere um espaço-tempo feito de uma série de loops entrelaçados em escalas mínimas de tamanho.

loops apenas perceptíveis na escala de Planck

espaço-tempo modular, que define o espaço-tempo pela maneira como os objetos interagem.

Assim, o espaço-tempo se torna uma consequência do próprio mundo quântico, não algo que precisa ser combinado com ele.

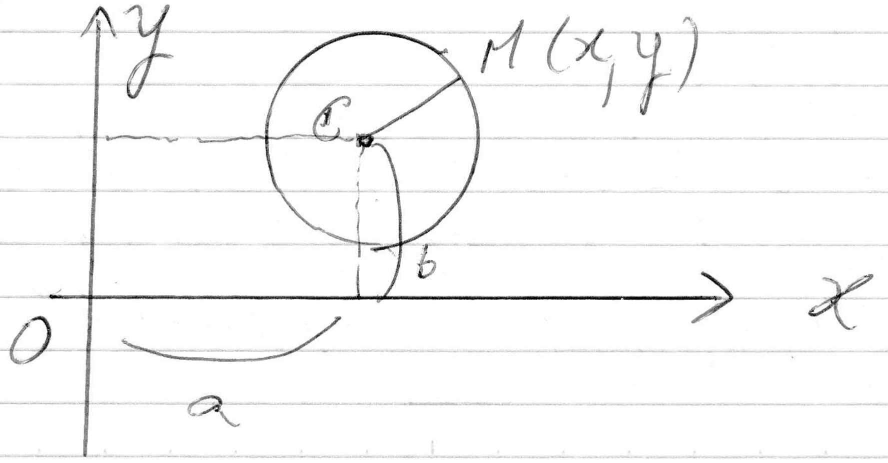
38 - the Circle



A circle of radius R with centre at the point C(a, b) is described by the equation

$$(x-a)^2+(y-b)^2=R^2$$

rewritten

$$x^2+y^2-2ax-2by+a^2+b^2-R^2=0$$

(20210725)

Mathematics Modern Calculus and Analytic Geometry. djvu (2012)

Pag. 527 (545)

Fig. 9.2

while $x^2+y^2=a^2$, with parametric representation

$$x=a\cos t,\quad y=a\sin t,\quad (0\leq t\leq 2\pi)$$

or

(cf Pag. 305)

There is nothing unique about the parametric representation of a curve

Ex:

$x = a \sin t,\ y = a \cos t \ (0 \le t < 2\pi)$
(2π)

or even

$x = a \cos \ln t,\ y = a \sin \ln t$
$(1 \le t \le e^{2\pi})$

represent the same circle

$$x^2 + y^2 = a^2$$

Um buraco negro é menor que o raio de Schwarzschild.

MIT – supercondutor chamado grafeno de três camadas torcidas por ângulo mágico.

→ tripleto de spin

↓

a energia de ambos os elétrons muda na mesma direção, mantendo a supercondutividade independente da intensidade do campo magnético ao qual estão submetidos.

3 camadas de grafeno e a camada do meio foi girada em 1,56 graus em relação às camadas externas.

ângulo gauss!

↳ curvatura

3 camadas torcidas poderá ser aplicado no desenvolvimento de computadores quânticos mais robustos.

Supercondutividade topológica
→ ingrediente chave para fazer isso seriam supercondutores de tripleto de spin.

O grafeno poderá ser usado para modular os sinais de telecomunicação em velocidades ultrarrápidas podendo ser utilizados para quaisquer frequências de comunicações desejadas

Grafeno ferroelétrico condutor
→ servirá para armazenar dados em memórias super rápidas para computadores

Grafeno →
uma das formas cristalinas do carbono,
organizado em uma forma camadas de átomos de carbono dispostos em hexágonos.

NB – Nitreto de Boro →

(dois)
Camada do meio entre 2 grafenos.
↳ ângulo ligeiramente diferente entre si.

→ Padrão moiré
(moiré)

→ padrão formado quando dois grafos apresentam movimento relativo entre si.

{ Padrão moiré
↳ compensa a curvatura espacial de Gauss?

→ important!!!

⇓

Primeiro ferroelétrico condutor,

"é a primeira demonstração que relata ferroeletricidade eletrônica pura, que exibe polarização de carga sem movimento iônico na rede subjacente". Philip Kim (Univ. Harvard).

Source:
(2) 8 unidades em 3D →
m01-3D-20210728-05.ggb

Checagem dos passos: (20210728)

A = (0, 0)
B = (0, 6)
C = (6, −3)
D = (6, 3)
E = (1, 1)
F = (7, −2)
G = (1, 7)
H = (7, 4)

f: Ray(A, E) → $-x+y=0$

g: Ray(C, F) → $-x+y=-9$

h: Ray(B, G) → $-x+y=6$

i: Ray(D, H) → $-x+y=-3$

Circles nos pontos A, B, C e D, usando o segmento $\overline{AB}$.

Ex:

c: Circle(A, Segment(A,B))
$\rightarrow x^2 + y^2 = 36$

d: Circle(B, Segment(A,B))
$\rightarrow x^2 + (y-6)^2 = 36$

e: Circle(C, Segment(A,B))
$\rightarrow (x-6)^2 + (y+3)^2 = 36$

k: Circle(D, Segment(A,B))
$\rightarrow (x-6)^2 + (y-3)^2 = 36$

Intersect das retas com os círculos:

I = Intersect(c, f, 1)
$\rightarrow (4.24, 4.24)$

J = Intersect(d, h, 1)
$\rightarrow (4.24, 10.24)$

K = Intersect(e, g, 1)
$\rightarrow (10.24, 1.24)$

L = Intersect(k, i, 1)
$\rightarrow 10.24, 7.24)$

Não deixe visível os Raios e os Círculos, deixando os pontos de intersecção visíveis para podermos fazer as retas do cubo.

Apague também os pontos (esconder):
E, F, G e H.

Erro:

Distância $\overline{AC} = 6{,}71$

tinha que ser 6,00

Vou refazer colocando

2 arestas sobre o eixo x e y.

(menos chance de erro)

Check 02 (20210728):

A = Intersect(xAxis, yAxis) -
⇒ (0, 0)

B = Point(xAxis) → (6, 0)

C = Point(yAxis) → (0, 6)

D = (6, 6)

—— 45°

E = (1, 1)

F = (7, 1)

G = (1, 7)

H = (7, 7)

Criar os Rays:

f: Ray(A, E) → $-x + y = 0$

Usarei a mesma reta no ponto D → continuidade da reta

Obs: a mesma reta AE continua em $\overline{DH}$.

g: Ray(B, F) → $-x + y = -6$

h: Ray(C, G) → $-x + y = 6$

——

Criar os círculos e as interseções sobre os Rays $\overline{AE}$, $\overline{BF}$, $\overline{CG}$ e $\overline{DH}$.

Usando a função COMPASS:

c: Circle(A, Segment(A, C))
→ $x^2+y^2=36$

d: Circle(B, Segment(A, C))
→ $(x-6)^2+y^2=36$

e: Circle(C, Segment(A, C))
→ $x^2+(y-6)^2=36$

k: Circle(D, Segment(A, C))
→ $(x-6)^2+(y-6)^2=36$

obs: Alterar as cores destes círculos.

Usar o comando Intersect:

I = Intersect(c, f, 1) → (4.24, 4.24)
J = Intersect(d, g, 1) → (10.24, 4.24)
K = Intersect(e, h, 1) → (4.24, 10.24)
L = Intersect(k, f, 2) → (10.24, 10.24)

obs: Esconda os círculos e os Rays, deixando apenas as interseções.

Depois, criaremos as retas do cubo.

Fazer os segmentos do Cubo:

i = Segmento(A, C) → 6 (altere a cor já)

j = Segment(B, D) → 6

Crie o ponto M=(3, 3)

Crie os novos segmentos:

l = Segment(C, M) → 4.24

m = Segment(M, D) → 4.24

n = Segment(A, I) → 6 (preto)

p = Segment(B, J) → 6 (preto)

q = Segment(C, K) → 6 (preto)

r = Segment(D, L) → 6 (preto)

s = Segment(I, K) → 6 (vermelho)

t = Segment(J, L) → 6 (Vermelho)

Novos comandos:

a: PerpendicularBisector(I, K) → y = 7.24

obs: Vale para o segmento s(I, K) e t(J, L)

Intersect:

N = Intersect(a, s) → (4.24, 7.24)

O = Intersect(a, t) → (10.24, 7.24)

Obs: Esconda a linha a.

Important: Crie.

b: PerpendicularBisector(N, O) → x = 7.24

Importante observar que este ponto coincide com a reta r (D, L) → somente na perspectiva.

Obs: reta a corta a reta r. (interseção visual, mas não real).

Criemos a interseção:

P = Intersect(a, b) → (7.24, 7.24)

Obs: Agora sim, esconda o segmento a e b.

Crie os segmentos:

f_1 = Segment(K, P) → 4.24 (vermelho)

g_1 = Segment(P, L) → 4.24 (vermelho)

Divisão de Segmentos:

Segmentos $\overline{CK}$ e $\overline{DL}$ com o Comando Bisector

h_1: PerpendicularBisector(C, K):
$\Rightarrow -4.24x - 4.24y = -43.46$

i_1 : Perpendicular Bisector(D, L):
$\Rightarrow -4.24x - 4.24y = -68.91$

Intersect :

R = Intersect(h_1, g) → (2.12, 8,12)
S = Intersect(i_1, r) → (8.12, 8.12)

Obs: Esconda h_1 e I_1.

Give Segment :

j_1 = Segment(R, S) → 6
k_1 : Perpendicular Bisector(R, S) ⇒
$x = 5.12$
T = Intersect(k_1, j_1) → (5.12, 8.12)
Esconda j_1 e k_1.

Outros comandos (base cubo)

data

I_1 : Perpendicular Bisector (A, I) →
$-4.24x - 4.24y = -18$

m_1 : Perpendicular Bisector (B, J) →
$-4.24x - 4.24y = -43.46$

Intersect:

U = Intersect(I_1, n) → (2.12, 2.12)

V = Intersect(m_1, p) → (8.12, 2.12)

n_1 = Segment(U, V) → 6

p_1 : Perpendicular Bisector (U, V) →
$x = 5.12$

W = Intersect(p_1, n_1) → (5.12, 2.12)

Obs: Apague o resto e deixe somente este ponto.

q_1 = Segment(I, W) → 2.3

r_1 = Segment(W, J) → 5.54

s_1 = Segment(K, T) → 2.3

t_1 = Segment(T, L) → 5.54

Other:

Segmento Inclinado:

a_1 = Segment(A, K) → 11.09

b_1 = Segment(B, L) → 11.09

c_1: Perpendicular Bisector(A, K) →

$-424x - 10.24y = -61.46$

d_1: Perpendicular Bisector(B, L) →

$-4.24x - 10.24y = -86.91$

Z = Intersect(c_1, a_1) → (2.12, 5.12)

A_1 = Intersect(d_1, b_1) → (8.12, 5.12)

e_1 = Segment(Z, A_1) → 6

f_2: Perpendicular Bisector(Z, A_1) →
$x = 5.12$

B_1 = Intersect(e_1, f_2) → (5.12, 5.12)

Important:

Os Pontos M, B_1 e P estão em linha reta.

Distância entre MP → 6 unidades.

Parte Final:

Crie a linha, ligando os pontos $\overline{KL}$

i_2 : Line (K, L) → y = 10.24

Criemos 3 segmentos com o comando Parallel Line baseado no segmento $\overline{AC}$ (6 unidades)

j_2 : Line(M, i) → x = 3

k_2 : Line(B_1, j_2) → x = 5.12

I_2 : Line(P, k_2) → x = 7.24 (7.24)

Intersect:

C_1 = Intersect(i_2, j_2) → (3, 10.24)

D_1 = Intersect(i_2, k_2) → (5.12, 10.24)

E_1 = Intersect(i_2, I_2) → (7.24, 10.24)

FINAL:

m_2 = Segment(M, C_1) → 7.24

> 2.12

n_2 = Segment(B_1, D_1) → 5.12

> 2.12

p_2 = Segment(P, E_1) → 3

q_2 = Segment(C_1, E_1) → 4.24 = soma

New simulators:

File: $m01-20210730-check-01-001.ggb$

c_2: Circle(B_1, M) →
$(x-5.12)^2+(y-5.12)^2=9$

Important:

3 Points:

1) Point P (7.24, 7.24)
2) Point B_1 (5.12, 5.12) e
3) Point M (3, 3)

→ Estes três pontos estão alinhados dentro do círculo c_2 e dois destes pontos estão sobre a circunferência.

Outros 3 pontos:

1) Point T(5.12, 812),
2) Point B_1(5.12, 5.12) e
3) Point W(5.12, 2.12)

→ 3 pontos alinhados e 2 pontos sobre a circunferência.

Todos os 6 pontos se encontram num mesmo ponto B_1, ou seja, as retas $\overline{PM}$ e $\overline{TW}$ fazem interseção no ponto B_1.

De acordo com Pappus Theorem observamos uma reta criada a partir de 3 pontos.
O ângulo entre estas retas é de 45°.

Obs: Simulação em 3D:

m01-3D-20210730-01.ggb

Usando a imagem 3D, utilizei o comando: Circle through 3 Points

Points: M_1, K_1, N_1

c_2: Circle(M_1, K_1, N_1) →

$$\to X = (4, 4, 4) + (0, -2.83\cos(t) - 2.83\sin(t), 2.83\cos(t) - 2{,}83\sin(t))$$

Localização dos pontos:

M_1 = Intersect(j_1, n_2) → (4, 8, 4)

K_1 = Intersect(b, m_2) → (4, 4, 8)

N_1 = Intersect(j, I_2) → (4, 0, 4)

Marcando as 2 retas que se intersectoram no ponto (B_1) J_1
↳2D ↳3D.

a) $M_1(j_1, n_2)$, $J_1(4,4,4)$ (m_2, g_2) e $N_1(j, I_2)$

$$\downarrow \qquad \downarrow \qquad \downarrow$$

(4, 8, 4)   (4, 4, 4)   (4, 0, 4)

b) $K_1(b, m_2)$, $J_1(m_2, g_2)$ e $L_1(s_1, r_1)$

$$\downarrow$$

(4, 4, 8)   (4, 4, 4)   (4, 4, 0)

20210801

Sir Chandrasekhara Venkata Raman, físico indiano que em 1930 se tornou o primeiro asiático a ganhar o Prêmio Nobel de Física.

Trabalho de Raman é centrado na dispersão da luz, que mostra que quando a luz atravessa um material transparente, parte da luz dispersada muda o comprimento de onda e amplitude, conhecido como

Efeito Raman princípio fundamental no campo da óptica

Ele descobriu que a cor do oceano é azul não por uma simples reflexão do céu, mas porque a água em si faz com que a luz azul se espalhe.

"A mathematician is a blind man in a dark room looking for a black cat which isn't there"

Charles Darwin

→ Não concordo, pois é a matemática que fornece a luz que desvenda toda a escuridão das outras áreas.

Stenio Murich.

Andrew Wiles

Andrew Wiles on what it feels like to do mathematics

jandaia

"Perhaps I could best describe my experience of doing mathematics in terms of entering a dark mansion.

One goes into the first room, and it's dark, completely dark.

One stumbles around bumping into the furniture, and gradually, you learn where each piece of furniture is, and finally after six months or so, you find the light switch.

You turn it on, and suddenly, it's all illuminated! You can see exactly where you were".

Pág. 46(80) 8. Topology

Poincaré who is certainly the major founder of the modern field of topology

First letter by Betti, dated October 6, 1863.

Betti then writes:

"What gave Riemann the idea of the cuts was that Gauss defined them to him, talking about other matters, in a private conversation. In this writings one finds that analysis situs, that is, the consideration of quantities independently from their measure, is "wichtig"; ..."

Pág. 101(134) - 3.1 Gauss

—

Pág. 100(133) →

This led Riemann to explain the difference between intrinsic and extrinsic properties of a surface.

He explained that for a sphere, which has an intrinsic geometry different from a plane, the

Gaussian curvature

multiplied by the area of an infinitesimal geodesic triangle is half the excess of the sum of its angles over π.

This allowed him to express the belief that the geometry of an n-dimensional manifold could be understood by understanding its sectional curvatures.

Pág. 142(174) theorem 2.2

If restricted to surfaces of Gauss curvature $K \leq 0$, then the surface is minimal if and only if its Gauss map is conformal.

Pag. 340(367) →

Pág. 241 (256) – Gauss Curvature

Fermat's principle of least time saying that the path take between two points by a light ray is the path which can be traversed in the least time. (60).

↳ Letter (January 1, 1662) to M. C. de la Chambre.

Employing it, he deduced the law of refraction.

Hence shortest curves on a surface are regarded as something similar to paths traced by light rays (see Sect 6.12)

and it is reasonable to say that a quantity (or a concept) attached to a surface is "intrinsic" if it is derived from distance and angle measured by using shortest curves.

Pág. 337 (352) →

Olinde Rodrigues (1795-1851)

Rodrigues is known for a formula

on this subject carrying his
name, and for

developing the idea of a
representation of a differentiable
surface on a sphere of radius
one which amounts to the
Gauss map.

He used such a (fal)

representation to study the ratio of
the area of (a piece of)
the original surface to the
area of its image on the
sphere.)

⟸

arriving
at a measure of curvature
which in fact is the

Gaussian Curvature

at a point of a surface

Pag. 448 (461) →

Husserl was confusing
intrinsic and extrinsic
natures of space.
He did not see to pay attention
to the fact that spheres and Euclidean
planes can be realised even in hyperbolic
space.

Map Projection

Pág. 497 (269) Appendix No. 15

A Quincuncial Projection of the Sphere

Orthomorphic or conform projection formed by transforming the stereographic projection, with a pole at infinity, by means of an elliptic function.

For that purpose, l being the latitude, and θ the longitude, we put —

$$\cos^2\varphi = \frac{\sqrt{1-\cos^2 l\cos^2\theta} - \sin l}{1+\sqrt{1-\cos^2 l\cos^2\theta}},$$

and then $\frac{1}{2}F\varphi$ is the value of one of the rectangular co-ordinates of the point on the new projection.

This is the same as taking —

$\cos \operatorname{am}(x+y\sqrt{-1})$ (angle of mod. $=45^\circ$) $=$ $\tan\frac{p}{2}(\cos\theta+\sin\theta\sqrt{-1})$, where

where x and y are the coordinates on the new projection, p is the north polar distance!

Wilhelm Blaschke e
T. Thomsen

New topic in differential geometry —
WEB GEOMETRY (Web Geometry)

→ Applications of ideas de Felix Klein to differential geometry.

Klein's "Erlangen program" (1872).

According to this program, every geometry studies properties of geometric figure that are invariant under transformations composing a certain group.

From this point of view, the

foundations of affine differential geometry and conformal differential geometry were presented in Blaschke's books, published in the 1920's.

Blaschke extende the same group-theoretic approach to web geometry.

→ pseudogroup

All differentiable transformations of a manifold, where a web is given, as a fundamental group, and studied local web invariants relative to transformation of this group.

Em minha pesquisa, haverá a projeção ortogonal (one-to-one) sobre um plano.

Pág. 97(97) - Chapter V
Coordinates in an Affine Plane with Desargues and Pappus Properties →

Affine Plane (incidence geometry)
Satisfy the following axioms:

- Any two distinct points lie on a unique line.
- Each line has at least two points.
- Given any line and any point not on that line, there is a unique line which contains the point and does not meet the given line. (Playfair's axiom)
- There exist three non-collinear points (points not on a single line)

In an affine plane, two lines are called parallel if they are equal or disjoint. (disjoint set)

Using this definition, Playfair's axiom above can be replaced by:

Given a point and a line, there is a unique line which contains the point and is parallel to the line.

Pág. 97 an affine plane is said to have the first Desargues property → parallel.

Groups, Matrices, and Vector Spaces...pdf

Pag. 211(221) – 7.3

Isometries and Orthogonal Mapping

The term orthogonal comes from the fact that an orthogonal mapping preserves the orthogonal relationship between orthogonal pairs of vectors.

Since orthogonal mapping preserve
inner products, they preserve the
lengths of vectors, distance between
vectors, and angles between vectors,
since the angle θ between

v and w is found by the
identity

$v \cdot w = |v| |w| \cos\theta$.

It turns out that all orthogonal
mapping are linear.

Important:

Pág. 41(45) 2.5 Axiomatic Design Theory. (ADT)

ADT uses two basic axioms as several other corollaries and theorems, to support the design theory.

First axiom is to maintaining the independence of FRs and the

Second axiom is to minimize the information content of the resulting design solution.

The act of design consists of the mapping of FRs into design parameters (DPs), and eventually to arrive at a solution, which satisfies these two axioms (axioms).

↘ Shape....pdf.epub

Pag. 173 – Cremona transformation is "a birational automorphism of projective space".

What is the ratio of the area of a size-zero square to its perimeter?

If the square has a side of length 1, that radio is 1/4 or 0.25.

When the side length shrinks to 1/2, the area is 1/4 and the perimeter is 2, so the ratio has gone down to 1/8.

side length 0.1, ratio is 0.01/0.4 or 0.025

... 0/0 = 0

Quantum Theory Bohm

The Quantum Dissidents

Cosmologia Quântica - um ramo da Física que tenta combinar Teoria Quântica com Gravitação, ou seja, Teoria Quântica com Teoria da Relatividade.

Efeitos Quânticos (Bohm) →

um deles Efeito Aharonov-Bohm

Emaranhamento Quântico e
Efeito Aharonov-Bohm

Einstein → Emaranhamento, ele chamava
"spooky action at a distance"

—

Bohm → outros Conceitos

a) Potencial Quântico
b) Totalidade
c) Ordem Implicada.

a) "Trata-se de uma função matemática que conecta instantaneamente partículas muito distantes"!

Tanto a Mecânica Quântica quanto o Potencial Quântico estavam sugerindo uma ideia de Totalidade.

Livro: Totalidade e o Universo Indiviso
(Bohm e Basil Hiley)

Niels Bohr estava certo, você não pode separar o observador do observado.

David Bohm introduziu o

conceito de Ordem –

a/ Ordem Implicada ou Implícita

b/ Ordem Explicada ou Explícita.

David Bohm e Jiddu Krishnamurti

Livro: ↙

"O observador é o observado!"

esposa de Bohm encontrou este livro. Int uma livraria.

Précis de géométrie.. Papelier...pdf

Pág. 292(301) Fig. 120.

Obs. Nº 380 - Tangentes à l'ellipse.

$x = a \cos \varphi; \quad y = b \operatorname{sen} \varphi;$

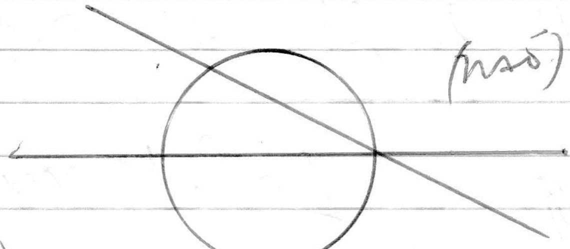
Obs: Ellipse usa estas equações para simular a deformação do espaço-tempo com as devidas adequações.

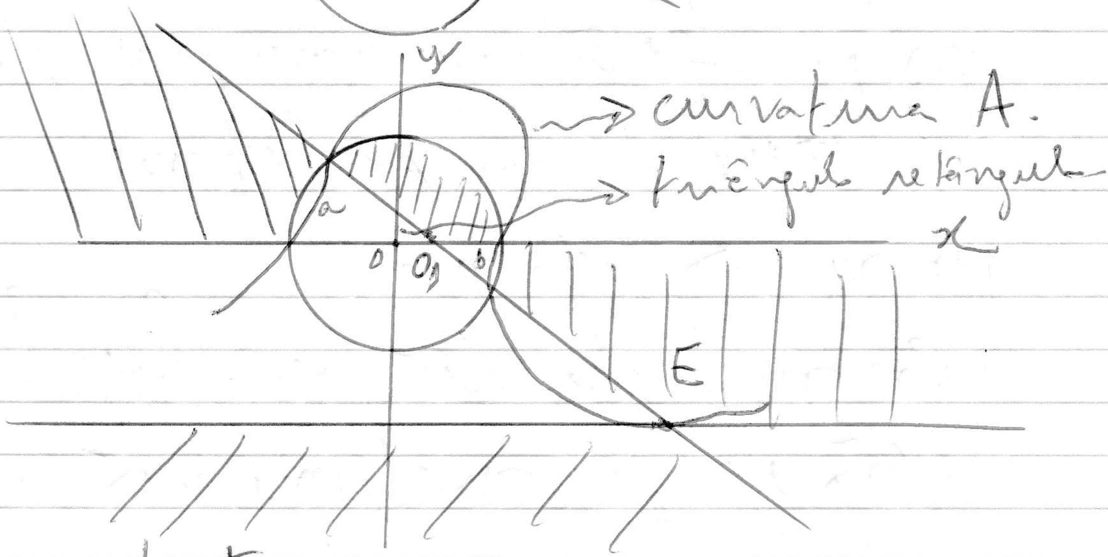
Na realidade a ellipse é uma deformação do círculo, ou seja, com os devidos ajustes das equações matemáticas podemos simular a curvatura do espaço-tempo do Universo.

Obs: $x = a \cos \varphi,$

$$y_1 = \frac{a}{b} y = a \operatorname{sen} \varphi$$

Pág. 201 (210) - Fig. 89





Important:

Estudar a razão entre $\underline{a \text{ e } b}$ em relação ao ângulo no ponto $\underline{O_1}$, observando se quando os dois são ângulos opostos, ou seja, tem o mesmo ângulo.

Veja como este comportamento matemático interfere na curvatura de $\underline{A}$, simule até obter a igualdade com a curvatura tempo-espaço do universo.

Observe que O e O_1 formam um triângulo retângulo (Pitagoras).

Use tudo isto com a ellipse do caso anterior para calcular a curvatura do Universo e que repercutiu no mesmo Mus (TT).

Obs: Estudar este livro todo!!

Pág. 16(33)

The curvature at a given point of a three-dimensional space is determined in the following manner.

A geodesic surface (analogue of a plane in Euclidean space) is drawn through the point, and its curvature is calculated. This curvature is called the Riemann curvature of space in the two-dimensional direction of the chosen surface. The curvature may be

different in different directions.
The curvature averaged over all directions is called the Gaussian curvature of the three-space.

Pág. 28(45) – Gaussian curvature (cf. § 1.4)

$$C_G = \frac{8}{3}\pi(G/c^2)\rho.$$

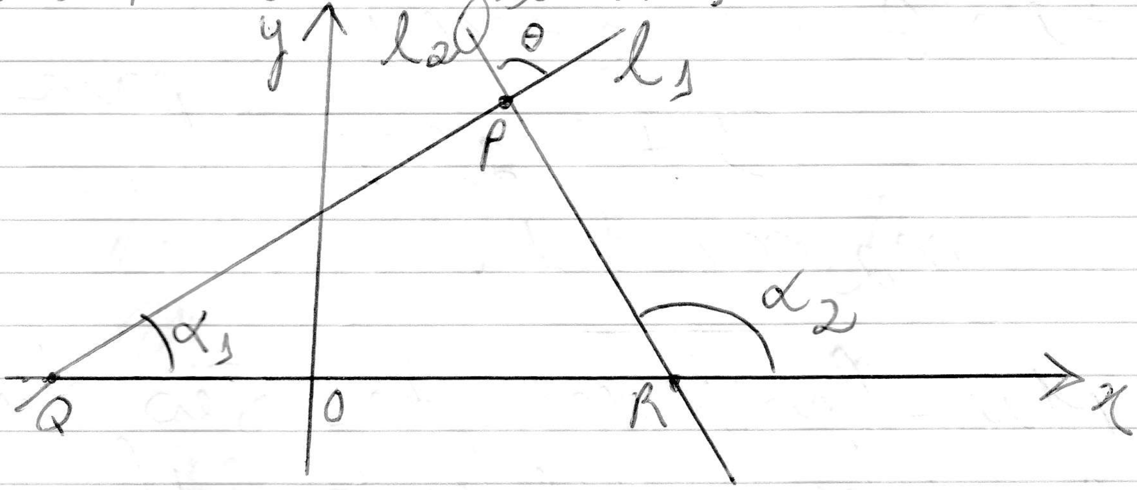
Pág. 127(137) —

Ángulo entre dos rectas

Los principios básicos de la geometría establecen que um ángulo exterior de um triángulo es igual a la suma de los ángulos interiores opuestos



$\alpha_2 = \alpha_1 + \theta$

Ángulo entre las rectas es:

$$\theta = \alpha_2 - \alpha_1$$

Al aplicar la fórmula trigonométrica

$$\tan(\alpha_2 - \alpha_1) = \frac{\tan\alpha_2 - \tan\alpha_1}{1 + \tan\alpha_2 \tan\alpha_1},$$ se tiene:

$$\tan\theta = \frac{\tan\alpha_2 - \tan\alpha_1}{1 \pm \tan\alpha_2 \tan\alpha_1}$$

Al substituir $m_1 = \tan\alpha_1$ y

$m_2 = \tan\alpha_2$

resulta:

$$\tan\theta = \frac{m_2 - m_1}{1 + m_2 m_1},$$ para

$m_2 m_1 \neq 1$.

One can trace the origin of such terms in the early works of GAUSS who measuring geodesic distances noted that scalar (Gauss) curvature of two dimensional surfaces depended only on the first fundamental form, in other words the intrinsic metric of the surface and its derivatives.

This was the basis of what he called the Egregium theorem; scalar curvature (unlike (diferente) other extrinsic curvature (components) does not depend on the variation of the normal vector field on the surface i.e. on how the surface is embedded in three dimensional space.

Then later, for Euler in his work on surface triangulations noted that two dimensional surfaces can be topologically classified by their "Euler" number,

$X: \chi[M] = 2-2h$ where h is

the number of topological handles.

Riemann geometry.

The tensor g equips the spacetime manifold M with a metric structure: it defines a distance between any two points, and this distance is a smooth function on M.

(More precisely, it defines a pseudo-metric structure, as distance can be imaginary).

Riemann studied the structure defined by (M, g), called today a riemannian manifold, and defined the Riemann curvature tensor as a generalization of Gauss' theory of curved surfaces to an arbitrary number of dimensions.

Riemann presented this mathematical theory as a general theory of "geometry" that generalized Euclidean geometry.

Einstein utilized this mathematical theory for describing the physical dynamics of the gravitational field.

Procurando por GAUSS neste livro eu encontrei na Pág. XIX (highlights) (19) no item 6, mas olhando o anterior:

5. The Remarks following 3.22 give an interesting analytic derivation of Archimedes' estimate of π and 3.28 outlines short elementary proofs of the irrationality of e and π.

Procurando por 3.22, encontrei:

Pág. 127(153) §3 The Complex Exponential Function.

Theorem 3.22 (Gregory-Leibniz series)

$$\frac{\pi}{4}=\int_0^1 \frac{dx}{1+x^2}=\sum_{n=0}^{\infty}\frac{(-1)^n}{2n+1}$$

Proof: ...

$$C\left(\frac{\pi}{4}\right)=S\left(\frac{\pi}{4}\right)=\frac{1}{\sqrt{2}} \longleftarrow$$

número errado!!!

Pág. 129(155) → (8)

$$\frac{\pi}{6} = \frac{1}{\sqrt{3}} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \cdot \frac{1}{3^n} . \quad (8)$$

Important: Pag. 129 (155)

(ii) Besides using the partial sums of the series or Riemann-sum approximations to the integral, there is a third (more efficient?) way to exploit 3.22 for rational approximations to π.

We get 1/630 > 22/7 − π > 1/1260, and so

$$3 + \frac{10}{71} < \frac{22}{7} - \frac{1}{630} < \pi < \frac{22}{7} - \frac{1}{1260} < 3 + \frac{1}{7}$$

///

His geometric construction can be found on pp. 31-34 of C. H. Edwards [1979].

Pág. 129(155) (iii) →

Yet a fourth way to utilize
3.22 is to express

$\pi/4 = \arctan(1)$ as a rational linear combination of

$\arctan(\varepsilon_j)$ for small ε_j

(for which the series is more rapidly convergent).

One of these goes back to Euler:

$$\pi/4 = 4\arctan(1/5) - \arctan(1/70) + \arctan(1/99).$$

Pag. 180 (206) –

3.22 inspired Leibniz to quote Virgil (on gambling!):

"Numero Deus impari gaudet".

Essentially the first equality in 3.22 was adopted by Weierstrass (in 1841) as his definition of π.

(This was also the definition adopted in the alternative treatment of the exponential function give in 2.22).

The present definition of π as "twice the least positive zero of the cosine function"

↗

"Apparently one man set out to vindicate another he will most likely do so regardless of the facts".

Gauss, Lobatchevsky and Bolyai (Pág. 413 (442)).

Undoubtedly thes (this) change accounts for the fact that three (men, Gauss, Lobatchevsky and Bolyai) with no knowledge of each other's thoughts, discovered the correct interpretation of Saccheri's work (at about the same time

Jandaia

Pag. 413(442)

Gauss was extremely modest. He said,

"If others would but reflect on mathematical truths as deeply and as continuously as I have, they would make my discoveries".

Those who believe that genius is 99 per cent perspiration as well as those who despair of their mathematical abilities may find comfort in Gauss's statement.

Gauss was still a youth when the problem of the parallel axiom first came to his attention.

Pag. 414(443)

Gauss's work on non-Euclidean geometry was found among his papers after his death.

Pag. 418(447) Gauss suggested a criterion for determining the truth of Euclidean Geometry.

The sum of the angles of a triangle equals 180° in this geometry but is less than 180° in the new geometry.

_ Morris Kline .. Nonmathematician (1985).pdf

Pág. 456(473) Gauss

He pursued the logical implications of a system of axioms which included the assumption that more than one parallel to a given line passed through a given point, and thus created non-Euclidean geometry.

Pág. 542(559)

Some of the axioms of Euclidean geometry are that two points determine a line, all right angles are equal, and the axiom on parallel lines.

The non-Euclidean geometry of Gauss, Lobatchevsky, and Bolyai contains the same axioms as Euclidean geometry does, except for the parallel axiom.

$\mathbb{R}^n$ is a topological space endowed with the topological $T = T_n$ induced by the distance d_n. As for any metrizable topological space, a subset U of $\mathbb{R}^n$ is open (i.e., it belongs to T) if and only if for every $x \in U$ there is $r > 0$ such that (de tal modo que) the "open" n-ball of centre x and radius r

Isometric embedding of surfaces.

An important well-known question is to characterize those ~~metric~~

intrinsic metric on a surface

which can be realized as embedding into three space.

Minkowski made the first major progress on this problem by proving that any convex polyhedron can be so realized [148].

Pag. 356 (366) B. Different geometries

One can study properties of surfaces that are invariant under a bigger group than the orthogonal group.

There are the special linear group, the conformal group and the projective group each acting on $\mathbb{R}^3$.

For affine geometry important invariants are the concepts of the affine metric (which is the second fundamental form divided by the fourth root of the GAUSSIAN curvature)

and the affine normal.

John Loftin discussed how to construct an affine sphere by a holomorphic section of the tricanonical line bundle of a Riemann surface.

Besse - Einstein Manifolds ... (1987).pdf

Obs. Gauss - 34 occurences

Pág. 02(13)   0.5 Introduction

Important:

For surfaces ($n=2$) the answer to the above question is known.

The best Riemannian structures on a given compact surface M are those of constant curvature.

In dimension 2, there is only one notion of curvature namely the Gauss curvature which its a function $K: M \to \mathbb{R}$. If M is embedded in $\mathbb{R}^3$

with the induced natural Riemannian metric the Gauss curvature is the product of the principal curvatures, or the inverse of the product of the principal radii (radii) of curvature. ...

Pag. 36 (47) 1.62 theorem

Given a Riemannian manifold (M, g), the function d is a distance on M, and the topology of the metric space (M, d) is the same as the manifold topology of M.

⇒ A corollary of the Gauss Lemma 1.46 is that the distance is realized (at least locally) by geodesics. More precisely.

Pag. 103 (114)

In other words, we have computed the curvature of 2-dimensional totally geodesic subspaces in Gaussian coordinates.

We can obtain the rest of the relevant sectional curvatures by observing that on each

ρ = constant hypersurface

$\mathbb{R} \times \{p\} \times S^2$ the induced metric is the product metric

$g_p = F^2(p)\, dt^2 - G^2(p)\, d\sigma^2$

...

Pag. 126(137) – 4.41 Remarks

If dim $M = 2$

a function f on M is the gaussian curvature of some metric if and only if f is positive somewhere (resp. is identically zero or takes both signs, resp. is negative somewhere).

F. The Manifold of Metric with Constant Scalar Curvature

Pag. 439(450) – 16.18

Thus each of the following conditions implies that the Riemannian manifold (M, g) has pure curvature operator:

(i) dim $M=2$, or $W=0$ (e.g., dim $M=3$, cf. 1.119);

(ii) (M, g) is a hypersurface in a space of constant curvature (cf. the Gauss equation (1.72 c));

(iii) (M, g) is a Riemannian product of manifolds with pure curvature operator.

Moreover, it is obvious that

(iv) the property of having pure Weyl tensor is conformally invariant.

Pág. 459(470)

On the other hand, the Gaussian curvature, K, of a surface

$u : \mathbb{R}^2 \Rightarrow \mathbb{R}$ in $\mathbb{R}^3$

(in the notation $u_x = \partial u/\partial x$ etc)

satisfies (12)

$$u_{xx} u_{yy} - u^2_{yy} - K(x, y)(1 + u_x^2 + u_y^2) = 0,$$

which is not quasilinear, it is fully nonlinear.

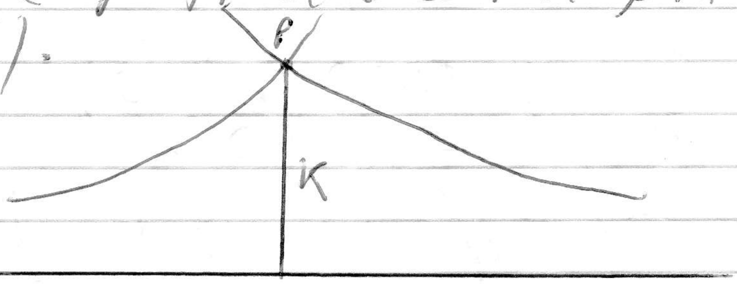
Pág. 153 (178) — 4.1.1 ⇙

The Advent of Hyperbolic Geometry

Characteristic Axiom of Hyperbolic Geometry

Given a line K and a point P not on K, there are at least two lines on P that do not intersect K (Fig 4.1).



Various consequences from this change, including the many that Saccheri found.

The most startling is the theorem that the measures of the angles of a triangle do not add up to π (or 180°), as they do in Euclidean geometry.

Pag 154 (179) theorem 4.1.1

In hyperbolic geometry the difference,

$$\pi - (m\angle A + m\angle B + m\angle C)$$

between π and the angle sum of a triangle is proportional to the area of triangle.

Pág. 160 (185) 4.1.4

Carl Friedrich Gauss

Gauss → regular 17-sided polygon

Obs: Exercises 4.1.9.

A common property of hyperbolic geometry is that two lines do not intersect and are not sensed parallel (described informally in Exercise 4.1.6) have a common perpendicular.

By 1800 Gauss had become convinced that Euclid's parallel postulate could not be proven, and in installments he developed what he called non-Euclidean geometry.

IMPORTANT:

Pág. 410 (435)

Gauss → they link the area of a triangle in spherical and hyperbolic geometry to their angle sums.

In the generalization, Gauss used geodesics for the sides of the triangles. Then, as he proved, the difference

Pag. 411 (436) cont.

between the angle sum of the triangle and π was determined by the area of the triangle and the curvature within it.

The sphere has constant positive curvature and the hyperbolic plane has constant negative curvature, accounting for the difference in theorems 1.5.3 and 4.1.1.

Obs: Página importante. ↙

Einstein
Riemann
Gauss

In 1854, Georg Riemann (1826-1866) generalized Gauss's results to any number of dimensions and so transformed differential geometry again.

Many mathematicians developed Riemann's insights into rigorous mathematics with computational methods.

Albert Einstein (1879-1955) built on Riemann's profound insights to revolutionize physics with the general theory of relativity.

Einstein needed a four-dimensional space built from three dimensions and time, all with varying CURVATURE corresponding to the strength of gravitational fields at different points.

Pag. 424 (449) 9.3

Surfaces and Curvature

From Gauss's definition of curvature, a sphere has constant positive curvature and a Euclidean plane has 0 curvature.

We often use the formula

$$\cos^2(\theta) + \sin^2(\theta) = 1$$

to simplify formulas for surfaces of revolution.

97. Let a an b be positive numbers with $a > b$.
Let a_1 be their arithmetic mean and b_1 their geometric mean:

$$a_1 = \frac{a+b}{2} \qquad b_1 = \sqrt{ab}$$

Repeat this process so that, in general,

$$a_{n+1} = \frac{a_n + b_n}{2} \qquad b_{n+1} = \sqrt{a_n b_n}$$

(a) Use mathematical induction to show that

$$a_n > a_{n+1} > b_{n+1} > b_n$$

(b) Deduce that both $\{a_n\}$ and $\{b_n\}$ are convergent.

(c) Show that $\lim_{n \to \infty} a_n = \lim_{n \to \infty} b_n$.

⇒ Gauss called the common value of these limits the arithmetic-geometric mean of the numbers a and b.

Jandaia

—

Pág. 811 (846) -

How Newton discovered the binomial series

$(a+b)^K$

Newton was the first to discover the infinite series expansion of $(a+b)^K$ when K is a fractional exponent (positive or negative).

He didn't publish his discovery, but he stated it and gave examples of how to use it in a letter (now called the epistola prior) dated June 13, 1676, that he sent to Henry Oldenburg, secretary of the Royal Society of London, to transmit to Leibniz.

11.11 Aplications of Taylor Polynomials

...

Pág. 817 (852) Figure 8

Depicts a wave from the point S meeting a spherical interface of radius R centered at C.

The ray SA is refracted toward P.

Important.

Using Fermat's principle that light travels so as to minimize the time taken, one can derive the equation

$$(1)\quad \frac{n_1}{l_0}+\frac{n_2}{l_i}=\frac{1}{R}\left(\frac{n_2 S_i}{l_i}-\frac{n_1 S_o}{l_o}\right)$$

where n_1 and n_2 are indexes of refraction l_o, l_i, S_o and S_i are the distances indicated in Figure 8.

By the Law of Cosines, applied to triangles ACS and ACP, we have

$$(2)\quad \begin{aligned} l_o &= \sqrt{R^2+(S_o+R)^2-2R(S_o+R)\cos\phi} \\ l_i &= \sqrt{R^2+(S_i-R)^2+2R(S_i-R)\cos\phi} \end{aligned}$$

Because Equation 1 is cumbersome to work with, Gauss in 1841, simplified by using the linear ~~[illegible]~~ approximation $\cos\phi \approx 1$ for small values of ϕ.

(This amounts to using the Taylor polynomial of degree (1). (Clear!!!

Then Equation 1 becomes the following simpler equation [as you are asked to show in Exercise 34(a)]:

Jandaia

(3) $\frac{n_1}{s_0} + \frac{n_2}{s_1} = \frac{n_2 - n_1}{R}$

the resulting optical theory is know as Gaussian optics, or first-order optics, and has become the basic theoretical tool used to design lenses.

Obs: A more accurate theory is obtained by approximating cos ϕ by its Taylor polynomial of degree 3

(which is the same as the Taylor polynomial of degree 2)

Important:

Usar isto para calcular o valor preciso observando-se a curvatura do tempo-espaço.

Usar toda esta sistemática destas equações para simular os diversos valores da curvatura do tempo-espaço e suas implicações sobre o TTTV (Mus).

This takes into accounts rays for which ϕ is not so small, that is, rays that strike the surface at greater distances h above the axis.

In Exercise 34(b) you are asked to use this approximation to derive the more accurate equation

(4) $$\frac{n_1}{s_o} + \frac{n_2}{s_i} = \frac{n_2 - n_1}{R} + h^2\left[\frac{n_1}{2s_o}\left(\frac{1}{s_o}+\frac{1}{R}\right)^2 + \frac{n_2}{2s_i}\left(\frac{1}{R}-\frac{1}{s_i}\right)^2\right]$$

the resulting optical theory is know as third-order optics.

Theory of geometrical construction

The proof of the irrationality of $\sqrt{2}$, as indicated by Aristotle and in "Elements" (X, 1 15), could be so interpreted that the diagonal of a given square ~~root~~ cannot be transferred towards one side by means of a purely linear operation.

...

algebraic solution → this was basically accomplished by Gauss, and the actual theory of geometrical constructions started with him.

Import:

In 1593 Vieta crowned his Supplementum geometricae with the proof that all problems that lead to equations of third or fourth degree become solvable if we, apart from compass and straightedge, allow instruments with which one can extract the third root of given quantities and trisect every angle.

Did Vieta know of the geometrical interpretation of complex algebra in Gauss's "complex number plane"?
⟹ Illus. 17.3.1
↳ Pag. 411 (424) ⟸ ✡

Pag. 412 (425) —

Algebraization of the theory of geometrical construction

Gauss ⇒ due to his discovery that the regular 17-gon can be constructed with compass and straightedge. (30/03/1796).

Further entries indicate that he came back to questions of circle division again and again, reduced to purely algebraic questions by using complex numbers, for the equation $x^n = 1$ (and/or after separating the trivial factor $x-1$ from x^n-1) for which n the equation $1+x+\ldots x^{n-1}=0$ can be solved by quadratic radicals

Pág. 413(426) - If angle trisection would be generally possible with compass and straightedge, then such is also the case in which the given angle is 60 degrees ...

The third famous ancient problem, squaring the circle, leads to an investigation under the new circumstances if number π is the root of a polynomial equation solvable by quadratic radicals.

Lambert showed the irrationality of π in 1767.

...

Ferdinand Lindemann finally generalized the idea of proof in 1882, i.e., he proved the transcendence of π meaning that π cannot at all be the solution of any algebraic equation with rational coefficients.

obs: Vahlen 1911 for mathematical details and a well-formed proof of transcendence of e and π.

Happy Birthday.

data

S T Q Q S S D

Hoje é aniversário de minha
querida Mãe Leda
90 anos

Que tristeza que ela não esteja
mais aqui entre nós, mas ela
está no céu!!!

Ela faleceu:
17 janeiro 2013

Ela está presente dentro de mim,
metade do meu DNA é dela.

Portanto, ela sempre estará
presente em minha vida.

Deus ama a todos!!!
Piedoso é
Misericordioso para com
todos!!!

Santo Agostinho – sementes
seminais
(matéria + evolucionismo)

Evolucionismo theológico
↳ teleológico

Big Bang ↖ Deus criou a matéria de uma vez e depois infundiu a evolução (mudança na forma da matéria).

→ Santo Agostinho disse que Deus criou a matéria e após isso colocou energia na matéria para que ela evolua.

Neste caso, não há incompatibilidade entre evolucionismo e criacionismo.

Darwinismo e Neo-Darwinismo.

↓ seleção natural

↓ alterações cromossômicas criam a evolução

FIM DE
2021

2022: Feliz Ano Novo!!!

There are four fundamental forces at work in the Universe:

(20220101)

1) The Strong force
2) The Weak force
3) The Electromagnetic Force
4) The Gravitational Force.

reflexo
(efeito)

The Gravitational Force é decorrência da "The Strong Force".

Se a gravidade existisse independentemente das demais forças, o Universo jamais terá sido criado pois antes do Big-Bang tudo estava reunido em um único ponto e portanto, a própria gravidade teria impedido a própria explosão do Big-Bang.

A gravidade deve ser analisada localmente e quando estendida, você terá outro valor.

A extensão da análise do fator gravitacional em relação a todo Universo gera uma curvatura ~~do~~ espaço-tempo.

O Universo se expande pois a "gravidade" age localmente em relação à cada galáxia e não em relação ao todo.

Deus é uma realidade, Ele existe por si mesmo e não depende da análise objetiva ou o entendimento das pessoas.

Deus pode ser entendido de várias formas de acordo com as convicções do homem que tenta entender Deus, mas não devemos fazê-lo de forma a conceituá-lo simplisticamente hermenêutico.

O nada existe.

O conceito do nada se reflete na criação da noção do número zero, criado na Índia, ou melhor, descoberto e esboçado na forma como conhecemos, primeiramente descoberto pois está realidade já existia, faltando somente a sua materialização no mundo fático ou "real", quando houve a retirada de uma pedra da sua posição matemática quando da resolução de uma operação matemática básica em que o espaço em que faltava a pedra, ou seja, o nada ou o zero existe independentemente da existência de uma pedra posicional para demarcar a existência daquele referido número.

O nada existe porque existe a Matemática

A Matemática existe por si mesma.

A Matemática é descoberta, o homem inventa a forma como nós descrevemos os conceitos matemáticos.

A Matemática tem várias facetas e nós podemos adequá-la a cada realidade existente e que por sinal é infinita, para poder entendê-la, mas a Matemática não pode ser distorcida ou corrompida pelo homem.

Na realidade, nós devemos tentar adequar a realidade à Matemática, pois para cada realidade nós teremos que conceituá-la de acordo com a Matemática imutável, cabendo a nós, meros mortais, inventar meios, métodos, formas para "tentar" descrever a nossa realidade dentro da Matemática.

Três premissas nós devemos ter em mente:

1) O nada sempre existiu, existe e existirá.
O nada é o reflexo oposto de Deus, uma face da mesma essência de Deus.
O Universo somente pode existir pois havia o nada.
A expansão do Universo também depende do nada.
O nada permitiu o Universo

se expandir, o nada implica que o Universo o preencha. O espaço decorre do nada, o espaço não é criado pelo Universo, mas alterado por este.

→ O Tempo sempre existiu, existe e existirá.
O tempo não é criado pelo Universo, mas alterado por este.

O nada existe e portanto, ele tem o seu próprio tempo e espaço.

2) A Matemática sempre existiu, existe e existirá.
A Matemática está em tudo para ser descoberta.
A realidade depende da Matemática, inclusive o seu próprio entendimento depende dela. Cabe a nós, descrever a realidade utilizando a Matemática.
A Matemática tem infinitas facetas e formas para descrever as infinitas realidade que ainda serão descobertas.

A Matemática e o nada decorrem de Deus.

O nada obriga, ou seja a criação de alguma coisa. /

O nada foi dado por Deus como a

chave que abre a porta para infinitas possibilidades.

O nada é como esta folha em branco na qual eu estou escrevendo. Esta página deseja ser preenchida pois se ela estivesse completa, o que eu poderia escrever para tentar inventar, descobrir, descrever, narrar, contar etc.

O tudo não permite a criação pois ele já ocupou tudo e não permite a inclusão de mais nada.

Deus é tudo. Ele não precisa dos homens e por isso, Ele criou o nada como uma forma de criar espaço para que o homem possa viver e sonhar.

Deus se "ausentou" e nos deu o "livre-arbítrio" para que nós, os homens possamos preencher o nada.

São Paulo 10 de fevereiro de 2022.

202202100240

20220210m

O nada existe.
O nada permite que o Universo exista.
Literalmente:

O Universo foi criado do nada.

O nada que existe, criou o Universo.

O nada criou condições para que o Universo fosse criado.

O nada criou o Universo, além dos confins do Universo, nós mesmos encontrar o nada.

O nada impulsiona o Universo a preenchê-lo de forma acelerada, ou seja, quanto mais nada temos, mais rápido o Universo tentará preenchê-lo.

O nada decorre de Deus.

O nada é a tábua rasa na qual Deus, permite ao homem interagir e existir.

O nada sempre existiu, mas pela sua essência, ele sempre se manifesta de infinitas formas, uma delas é o Universo que conhecemos.

O nada por si mesmo cria
condições para que algo decorra
dele.

O Universo não foi criado,
ele é a manifestação do
nada.
(uma das manifestações).

O nada existe,
somente o que existe,
poderá criar algo,
neste caso,
o Universo.

O nada também é uma forma
de energia.

Tudo é energia,
a falta de energia também
é uma forma de energia.

NOTHING IS ALL

=

20220212 III 0003

A gravidade como força independente não existe.

A gravidade decorre da força forte (lei fundamental da física)

A curvatura do tecido espaço-tempo decorre da Força Forte.

A soma de cada Força Forte de cada átomo reunido em um determinado espaço gera por conseqüência a ação gravitacional. Quanto mais átomos, mais forte será a soma das Forças Fortes de todos os átomos reunidos em determinado espaço, que por sua vez, irá distorcê-lo de acordo com a reunião de todas as Forças Fortes de todos os átomos reunidos em um determinado espaço.

A curvatura do Universo existe e decorre de toda a massa deste Universo.

Onde não há massa no Universo, existe uma mínima curvatura que é decorrente da massa do Universo como um todo.

O nada existe, como o vazio do Universo também existe.

A existência destes dois gera também uma força!!!

A força gerada pelo nada e pelo vazio decorre de simetria intrínseca existente o Tudo (Deus) e o nada.

A Entropia decorre desta interação simétrica destes dois elementos.

A falta de paridade de aniquilação entre matéria e anti-matéria decorre da interação intrínseca da ação simétrica entre estas duas forças universais atuantes no Universo analisado. (em carta)

A falta desta paridade ou simetria decorre da interação entre o tudo e o nada, ou seja, não se trata de falta de paridade mas a ação permanente do equilíbrio entre estas duas forças que interagem na criação e destruição do Universo.

entraremos no campo da filosofia e da religião. Deus Shiva na cultura indiana. (estudar!!!) 20200212 0018

20220306m

202202060005

$1^3 = 3$ ou 4

$1 \times 1 \times 1 = \boxed{3}$ (3 unidades)

$\underbrace{(01) \quad (02) \quad (03)}_{\text{3 unidades}}$

Usando da mesma lógica:

$2^3 = 8$

$\underbrace{2 \times 2 \times 2}_{\text{3 elementos}} = 8$ (valor em unidades)

O número 2 é o dobro de 1, portanto, se $2^3 = 8$ e o número 1 é a metade de 2^3, portanto, $1^3 = \boxed{4}$

Prosseguindo (com base na razão no número qual (exponenciando)

~~2~~ $3^3 = 27$

$3 \times 3 \times 3 = 27 \Rightarrow 1 = \frac{1}{3}$ de 27

$\frac{27}{3} = \boxed{9}$

$4^3 = 64 \Rightarrow 1 \Rightarrow \frac{1}{4}$ de $64 = \frac{64}{4} = \boxed{16}$

$5^3 = 75 \Rightarrow 1 = \frac{1}{5}$ de $125 = \frac{125}{5} = \boxed{25}$

$6^3 = 216 \Rightarrow 1 = \frac{1}{6}$ de $216 = \frac{216}{6} = \boxed{36}$

$7^3 = 343 \Rightarrow 1 = \frac{1}{7}$ de $343 = \frac{343}{7} = \boxed{49}$

$8^3 = 512 \Rightarrow 1 = \frac{1}{8}$ de $512 = \frac{512}{8} = \boxed{64}$

$9^3 = 729 \Rightarrow 1 = \frac{1}{9}$ de $729 = \frac{729}{8} = \boxed{81}$

$10^3 = 1000 \Rightarrow 1 = \frac{1}{10}$ de $1000 = \frac{1000}{10} = \boxed{100}$

Divisão por $\underline{\underline{4}}$:

$1 \times 1 \times 1 = 4$

$2 \times 2 \times 2 = 8 \; \rangle \; \frac{8}{4} = 2$ (dobro)

$3 \times 3 \times 3 = 27 \; \rangle \; \frac{27}{8} = 3{,}375$

$4 \times 4 \times 4 = 64 \; \rangle \; \frac{64}{27} = 2{,}\overline{370}$

$5 \times 5 \times 5 = 125 \; \rangle \; \frac{125}{64} = 1{,}953125$
(1,953125)

$6 \times 6 \times 6 = 216 \; \rangle \; \frac{216}{75} = 2{,}88$

$7 \times 7 \times 7 = 343 \; \rangle \; \frac{343}{216} = 1{,}58796286$

$8 \times 8 \times 8 = 512 \; \rangle \; \frac{512}{343} = 1{,}49271137$

$9 \times 9 \times 9 = 729 \; \rangle \; \frac{729}{512} = 1{,}42382812$

$10 \times 10 \times 10 = 1000 \; \rangle \; \frac{1000}{729} = 1{,}37174211$

entre os números reais

$\cong \sqrt{2} = 1{,}414217?$

Relação direta entre os números.

$1 \rightarrow 2 \Rightarrow 8 \div 4 = 2$

$1 \rightarrow 3 \Rightarrow 27 \div 4 = 6,75$

$1 \rightarrow 4 \Rightarrow 64 \div 4 = 16$

$1 \rightarrow 5 \Rightarrow 125 \div 4 = 31,25$

$1 \rightarrow 6 \Rightarrow 216 \div 4 = 54$

$1 \rightarrow 7 \Rightarrow 343 \div 4 = 85,75$

$1 \rightarrow 8 \Rightarrow 512 \div 4 = 128$

$1 \rightarrow 9 \Rightarrow 729 \div 4 = 182,25$

$1 \rightarrow 10 \Rightarrow 1000 \div 4 = 250$

$6,75 - 2 = 4,75$

$16 - 6,75 = 9,25$

$31,25 - 16 = 15,25$

$54 - 31,25 = 22,75$

$85,75 - 54 = 31,75$

$128 - 85,75 = 42,25$

$182,25 - 128 = 54,25$

$250 - 182,25 = 67,75$

Se em vez de 4 → 3

$1 \times 1 \times 1 = 3$

$8 \div 3 = 2,\overline{6}$

$27 \div 3 = 9$

$64 \div 3 = 21,\overline{3}$

$125 \div 3 = 41,6$ (41,6)

$216 \div 3 = 72$

$343 \div 3 = 114,\overline{3}$

$512 \div 3 = 170,6$

$729 \div 3 = 243$

$1000 \div 3 = 333,\overline{3}$

$4,75 \rangle 4,5$

$9,25 \rangle 6$

$15,25 \rangle 7,5$

$22,75 \rangle 9$

$31,75 \rangle 10,5$

$42,25 \rangle 12$

$54,25 \rangle 13,5$

$67,75$

diferenças de 1,5 em ⑴,5 N

Voltando:

$1^3 = 4 \leftarrow \left(\frac{8}{2} = 4\right)$

$2^3 = 8 \rightarrow 2$ é o dobro de ①

$1^3 = 4$

$2^3 = 8 \rightarrow$ 2 é o dobro 1 $= 8 \div 4 = 2$

$3^3 = 27 \rightarrow$ 3 é o triplo 1 $= 27 \div 4 = 6{,}75$

$4^3 = 64 \rightarrow 4 \times 1 = 64 \div 4 =$

$5^3 = 125 \rightarrow 5 \times 1 = 125 \div 4 =$

$6^3 = 216 \rightarrow 6 \times 1 = 216 \div 4 =$

$7^3 = 343 \rightarrow 7 \times 1 = 343 \div 4 =$

$8^3 = 512 \rightarrow 8 \times 1 = 512 \div 4 =$

$9^3 = 729 \rightarrow 9 \times 1 = 729 \div 4 =$

$10^3 = 1000 \rightarrow 10 \times 1 = 1000 \div 4 =$

Corrigindo

$8 \div 4$ = erro

✡

$8 \div 2 = 4 \div (1^3)$ > 5

$27 \div 3 = 9$ > 7

$64 \div 4 = 16$ > 9

$125 \div 5 = 25$ > 11

$216 \div 6 = 36$ > 13

$343 \div 7 = 49$ > 15

$512 \div 8 = 64$ > 17

$729 \div 9 = 81$ > 19

$1000 \div 10 = 100$

~~outro erro~~ NAO!!

Correto

O valor aumenta de 2 em 2

conjuto:

Usando a multiplisação partindo-se do número $1^3 = 4$, depois faremos $1^3 = 3$ //

$$1^3 = \boxed{4}$$

2x

$$2^3 = \boxed{4} \times 2 = 8$$

×3

$$3^3 = \boxed{4} \times 3 = 12$$

$$4^3 = \boxed{4} \times 4 = 16$$

$$5^3 = \boxed{4} \times 5 = 20$$

$$6^3 = \boxed{4} \times 6 = 24$$

$$7^3 = \boxed{4} \times 7 = 28$$

$$8^3 = \boxed{4} \times 8 = 32$$

$$9^3 = \boxed{4} \times 9 = 36$$

$$10^3 = \boxed{4} \times 10 = 40$$

mantendo-se
a proporção,
(o ensinamento
equivocado com
potenciação)

estudar!!!

mas numericamente
está correto.
(?)
Checar!!!

Valores reais:

4 $8 \div 4 = 2$
8
27 $27 \div 4 = 675$
64 $64 \div 4 = 16$
125 $125 \div 4 = 31,25$
216 $216 \div 4 = 54$
343 $343 \div 4 = 85,75$
512 $512 \div 4 = 128$
729 $729 \div 4 = 182,25$
1000 $1000 \div 4 = 250$

discrepância.

Simulações:

$1^3 = 1 \times 1 \times 1 = 3$

$2^3 = 2 \times 2 \times 2 = 8$ } $8 \div 3 = 2,\overline{6}$

$3^3 = 27 \rightarrow 27 \div 3 = 9$

$4^3 = 64 \rightarrow 64 \div 3 = 21,\overline{3}$

$5^3 = 125 \rightarrow 125 \div 3 = 41,\overline{6}$

$6^3 = 216 \rightarrow 216 \div 3 = 72$

$7^3 = 343 \rightarrow 343 \div 3 = 114,\overline{3}$

$8^3 = 512 \rightarrow 512 \div 3 = 170,\overline{6}$

$9^3 = 729 \rightarrow 729 \div 3 = 243$

$10^3 = 1000 \rightarrow 1000 \div 3 = 333,\overline{3}$

Aprofundando:

começando desde o número

1

$1^3 = 4$

$1^3 = 4 \Rightarrow 4 \div 1 = 4$

$4 - 4 = 0$

relação direta perfeita!!! (ou relação direta)

$2^3 = 8 \Rightarrow 8 \div 2 = 4$ > 5

$3^3 = 27 \Rightarrow 27 \div 3 = 9$ > 7

$4^3 = 64 \Rightarrow 64 \div 4 = 16$ > 9

$5^3 = 125 \Rightarrow 125 \div 5 = 25$ > 11

$6^3 = 216 \Rightarrow 216 \div 6 = 36$ > 13

$7^3 = 343 \Rightarrow 343 \div 7 = 49$ > 15

$8^3 = 512 \Rightarrow 512 \div 8 = 64$ > 17

$9^3 = 729 \Rightarrow 729 \div 9 = 81$ > 19

$10^3 = 1000 \Rightarrow 1000 \div 10 = 100$

aumento de 2 em 2

Obs:

Mantendo-se esta constante e retroagindo até o número 1,

$1^3 = 1$, pois $2^3 = 8 \div 2 = 4$

$4 - 3 = 1$

e não $1^3 = 3$ ou 4

data

S T Q Q S S D

Comparando ⇒ 3 e 4

Prescribing the curvature of a Riemannian Manifold

Jerry L. Kazdan n°57

Michel Serres - Geometry

---

libgen.is

20220424 M Biologia quântica.

Os processos biológicos são na verdade sistemas quânticos.

Os processos biológicos são muito complexos.

Os sistemas quânticos precisam de "estabilidade" algo que os cientistas conhecem como coerência de ondas.

A biologia tem condutores de energia. Este processo realmente existe e é chamado de tunelamento.

As partículas se movem na forma de ondas.

Pesquisador: Erwin Schrödinger
(1/2 séc. 20)

— tunelamento.
— spin.

Fotossíntese — 3 etapas:

1) Captura do fóton (a partícula portadora da radiação eletromagnética) pelas plantas.

2) elétrons absorvem a energia dos fótons e passam para um estado de maior energia navegando pelas moléculas e com base no efeito túnel.

3) O elétron é usado para uma reação química que resulta na liberação de oxigênio.

obs. dependendo do spin

Dependendo da direção do spin o elétron passará ou não pelo túnel.

QUIRALIDADE (grego kheir)

⇒ mão.

Quando um objeto é quiral, tem outro que o seu reflexo.

Isso significa que o spin anda de mãos dadas com o quiral.

Portanto:

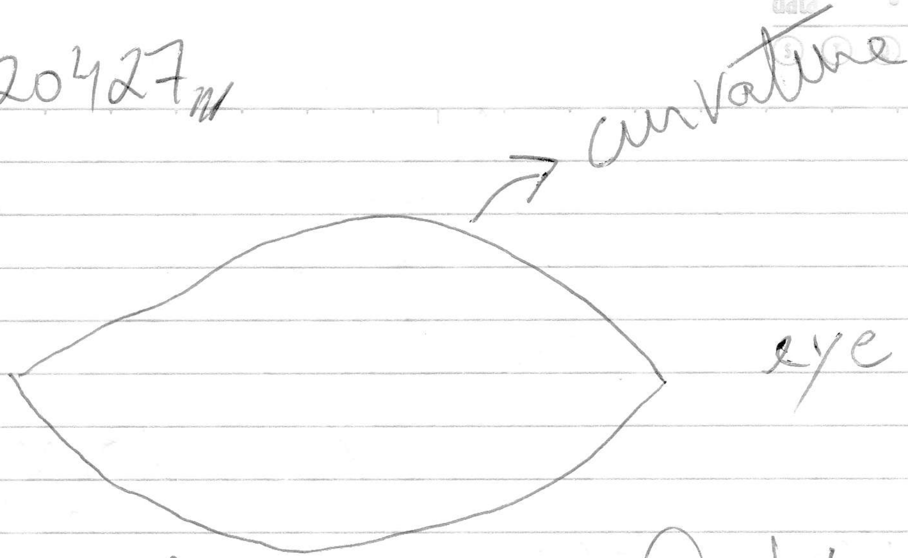
1/ Entrelamento
2/ spin
3/ quiralidade

Presente: a/ fotossíntese
b/ síntese de proteínas
c/ a forma como os organismos respiram
d/ conexão entre os neurônios.
e/ mutações.

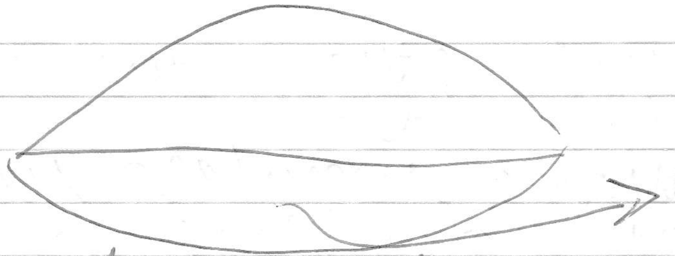
---

quiralidade → chirality
(Kheir greek world)

20220427

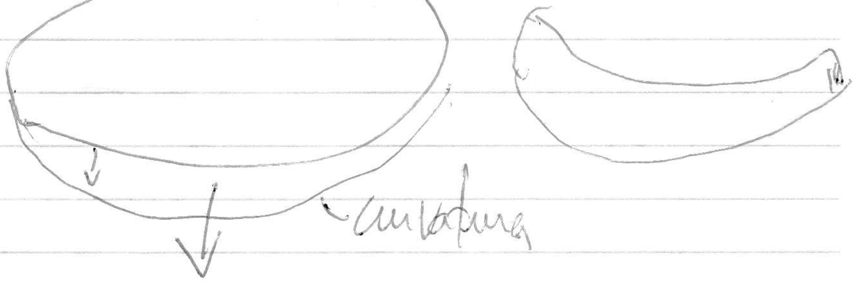


Manipular as equações até conseguir obter um círculo.

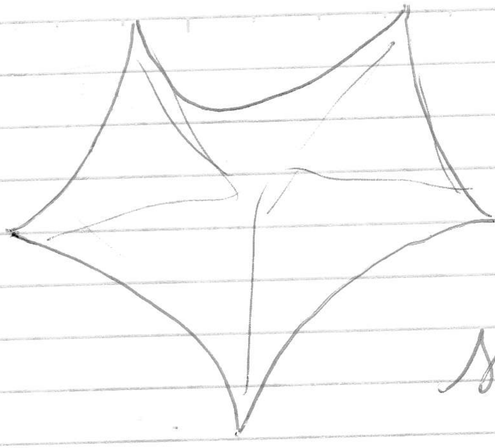


o parte de baixo tem uma curvatura, simular para obter a mesma curvatura de Gauss (Universe).

Fazer uma simulação que represente um círculo curvo desenhado sobre um plano.



data



pentagrama
(curvo)

(3D)

sobre um
plano.

Fazer a mesma
simulação com um círculo.
(círculo curvo).

—

Criar uma equação que crie
um círculo perfeito.

Esta equação simulará um
círculo curvo com "projeção" (mirror)
ortogonal sobre um plano, ou seja,
esta equação servirá para a
prova do nosso valor de Pi = MVS.

Desta forma, será um círculo
curvo em (3D) com espelhamento
ortogonal sobre um plano.

Séc. XIX / Henri Poincaré

Objetos homeoformos.

Algumas pessoas se referem a esse importante campo da matemática como "geometria flexível", ou seja, duas formas são a mesma se for possível transformar uma em outra sem quebrá-la!

Poincaré → desenvolveu todas as formas possíveis nas quais poderia envolver esse universo bidimensional plano.

Conjectura Poincaré → aplicar para o mundo 3D.

Grigori Perelman → 1994
havia provado a "conjectura da alma",
segundo a qual pode-se deduzir as propriedades de um objeto matemático a partir de pequenas regiões desses objetos, chamados alma.

Hamilton → 1982
"Fluxo de Ricci" com a qual se suspeitava ser possível comprovar a conjectura de Poincaré.

Tarefa era extremamente técnica
e sua execução, complicada.

Perelman ⇒ 1993
aceitou uma bolsa de pesquisa
na Universidade da Califórnia,
onde assistiu a várias conferências
de Hamilton.

The largest n-digit number
that is also an nth power
21 digits

$9^{21} = 109,418,989,131,512,359,209$

$2592 = 2^5 \times 9^2$

Also the ratio between
1 mi and 1 km is very close
to the Golden Ratio ≈ 1.61

Tutte Polynomial

called the dichromate or Tutte-Whitney polynomial.

The Tutte Polynomial is a polynomial in two variables x y which can be defined for a graphic, matrix, or, even more generally, a matroid.

$E = mc^2$

Nesta formula, quanto mais rápido um objeto viaja, maior fica a sua massa, pois ele tem que gastar energia e aplicar força para acelerar.

Lembre-se que conforme você coloca força maior é a massa do objeto e portanto novos calculos deverão ser feitos.

A energia necessária é calculada sempre com a nova massa.

Para uma grande massa acelerar do mesmo jeito, a massa precisará de uma força muito maior, indicando que a massa e energia são inseparáveis.

1915 - Einstein alterou a Gravidade de Newton.

A gravidade não era uma força e concluiu que a Terra girava ao redor do Sol devido à geometria do Universo, que é deformada pelo astro.

Grandes massas criam curvaturas significativas na malha do espaço-tempo, acarretando a atração dos corpos menores.

Massa + Equações de Maxwell

20220515/
Maxwell equations/

Lei Newton

$F = m a$

A energia para acelerar um objeto com massa m também é massa, pois há uma correlação direta entre massa e energia.

—

Teoria dos conjuntos causais
→ "átomos de espaço-tempo".
→ resolve a questão de singularidade

Ideia da "transformação assincrônica"
→ os elementos nascem de forma parcial e não total.

—

→ Princípio da simetria da mecânica quântica.

As simetrias descrevem características do espaço-tempo e partículas que permanecem inalterados apesar de ter havido alguma transformação.

→ "Universo Espelho".

→ 'anti-universo'.

↳ o tempo corre para trás e a antimatéria é dominante.

Desta forma, a simetria seria cumprida.

O universo espelho ofereceu uma explicação para a matéria escura.

Big-Bang → matéria-escura ⇒ "neutrinos destros".

20220531

$\left(\frac{3}{1.129}\right)\hat{}\;1.129 = 3{,}01424\ldots$

$\left(\frac{3}{1.128}\right)\hat{}\;1.128 = 3{,}014311\ldots$

$\left(\frac{3}{1.1284}\right)\hat{}\;1.1707 = 3{,}14157\underline{7}4$

(obs. $1.1708 = 3{,}1418\ldots$)

Estudar:

$\left(\frac{3}{1.1284}\right)\hat{}\;1.170706 = 3{,}14159267\underset{(535)}{\underline{77}}$

Obs:

$\left(\frac{3}{1{,}132}\right)\hat{}\;1.132 = 3{,}014\ldots\ldots 0500$

(muito interessante)

Ver depois!!!

Aprofundando:

$\left(\frac{3}{1.1284}\right)\hat{}\;1.170705 \cong 3{,}1415896\ldots$

→ repetiu padrão.

$3{,}1415926535\underset{(9)}{83}$

Voltando um pouco:

$\left(\frac{2}{1.1284}\right)$ ^ 2 = 3,14147766 .... 630 (par)

↓ até

2.00006 ≅ 3,1415845...

Comparar

$\left(\frac{3}{1.1284}\right)$ ^ 1,17070~~6~~ ≅ 3,1415742...

$$\begin{array}{r} 2.0006 \\ -\ 1.1707 \\ \hline 0,8299 \end{array}$$ (?)

expandido:

1,17070 $\boxed{59921}$ 2

checar!

checar se dá 6000...

$$\begin{array}{r} 2.00006 \\ 1.70706 \\ \hline 0,2930 \end{array}$$ ⇒ final par.

$$\left(\frac{2}{1.1284}\right)^{\wedge}2.0000599 \cong 3,1415843551$$

$$\left(\frac{3}{1.1284}\right)^{\wedge}1.17070599 \cong 3,1415926470$$

$$\begin{array}{r} 2.0000599 \\ 1.17070599 \\ \hline 0,82935391 \end{array}$$

$$\left(\frac{2}{1.1284}\right)^{\wedge}2.0000599 = 3,1415843551$$

$$2.00000599 = 3,1414874224$$

Comparar:

$$\left(\frac{3}{1.1284}\right)^{\wedge}1.170706 = 3,1415926777$$

$$1.17070599 = 3,1415926470$$

$$\left(\frac{2}{1.1284}\right)^{\wedge}2 = 3,1414766523$$

$$\left(\frac{3}{1.1284}\right)^{\wedge}1,1707 = 3,1415742465.$$

$$\therefore \left[\left(\frac{3}{1.1284}\right)^{\wedge}1,1707\right] - \left[\left(\frac{2}{1.128}\right)^{\wedge}2\right] =$$

$$0,00009759\ldots$$

$\left(\frac{2}{1.1284}\right)^{\wedge} 2.0000599 =$

$2.\underbrace{0000}_{(4)}599 = 3{,}1415843551$

$\left(\frac{3}{1.1284}\right)^{\wedge} 1{,}1707 = 3{,}14\underline{\underline{157424}}65$

∴

$\left(\left(\frac{2}{1.1284}\right)^{\wedge} 2.0000599\right) - \left(\left(\frac{3}{1.1284}\right)^{\wedge} 1{,}1707\right) =$

$0{,}000101086$

Invertendo a ordem

$\left(\frac{3}{1.1284}\right)^{\wedge} 1.17070599 -$

$\left(\frac{2}{1.1284}\right)^{\wedge} 2.0000599 =$

$0{,}000000829188335....$

Important:

Você mantendo a constante

$\left(\frac{2}{1.1284}\right)^{\wedge} 2.0000599$ e

alterando a segunda parte,

da equação, obteremos o seguinte:

a) Quando

$\left(\frac{3}{1.1284}\right)^{1.1707}$, obtemos que a fração

$\left(\frac{3}{1.1284}\right) < \left(\frac{2}{1.1284}\right)$ (menor na equação)

embora

$\frac{3}{1.1284} \cong 2,658$ seja maior

$\frac{2}{1.1284} \cong 1,771$

b) Quando alteramos o exponencial de 1.1707 para 1.17070599, obteremos o seguinte

$\left(\frac{3}{1.1284}\right) > \left(\frac{2}{1.1284}\right)$

Em resumo:

Na hipótese (a) a diferença de valor entre uma equação e outra é de

0,000101086...

Na hipótese (b) a diferença é muito menor:

$$0,\underbrace{00000}_{(5)}829188335...$$

Analizando mais profundamente veremos o seguinte:

$$\left[\left(\frac{2}{1.1284}\right)^{\wedge}2.0000599 - \left(\frac{3}{1.1284}\right)^{\wedge}1.1707\right] - \left[\left(\frac{3}{1.1284}\right)^{\wedge}1.17070599 - \left(\frac{2}{1.1284}\right)^{\wedge}2.0000599\right] =$$

$$0,000001816774722...$$

Interessante:

A mudança de ordem ocasionou um número interessante

$-6,2831$

(2π negativo) → como em um espelho (mirror)

Equação:

~~$\left(\frac{2}{1.1284}\right)$ ^ 1.17070599~~ $\cancel{=}$

$\left(\frac{2}{1.1284}\right)$ ^ 2.0000599 $-$

$\left(\frac{3}{1.1284}\right)$ ^ 1.1707 $-$

$\left(\frac{3}{1.1284}\right)$ ^ 1.17070599 $-$

$\left(\frac{2}{1.1284}\right)$ ^ 2.0000599 $=$

$= 6,28316689\ldots$ $(= -2\pi)$

obs $6,28318530\ldots$ $(= 2\pi)$

Estudar e inverter a ordem...

Arrumando para facilitar: (Ajustando)

$\left(\frac{3}{1.1284}\right)$^1.17070599 −

$\left(\frac{3}{1.1284}\right)$^1.1707 − → 599

$\left(\frac{2}{1.1284}\right)$^$2.0000\textcircled{6}$ − → 599

$\left(\frac{2}{1.1284}\right)$^$2.0000\textcircled{6}$ =

−6,2831506..

Alterando ⇓

2.00006 → 2.0000599

∥ ✓

= −6,283150309...

Obs: Na folha anterior tínhamos a seguinte ordem.

2 3 3 2

Nesta 3 3 2 2

Obs: Há uma diferença de valores.

Na página anterior:

$\rightarrow 6,28316689$

Nesta:

$\rightarrow 6,283150309\ldots$

Obs: Há um erro (checar!!!)

Em detalhes: (item por item depois)

① Interessante tirando o último item, observamos:

$\left(\frac{3}{1.1284}\right)^{1.17070599} -$

$\left(\frac{3}{1.1284}\right)^{1.1707} -$

$\left(\frac{2}{1.1284}\right)^{2.0000599} =$

$\rightarrow 3,1415659\ldots$

recolocando o último item

$\left(\frac{2}{1.1284}\right)^{2.0000599}$ na primeira parte desta equação. Temos

$\rightarrow 6,28316689\ldots$

Alterando os valores:
2.0000599 para
2.00006
e fazendo alguns ajustes:

$$\left(\frac{2}{1.1284}\right)^{\wedge}2.00006-\left(\frac{3}{1.1284}\right)^{\wedge}1.170708 -$$

$$\left(\frac{3}{1.1284}\right)^{\wedge}1.1707-\left(\frac{2}{1.1284}\right)^{\wedge}2.00006 =$$

-6,2831730
(853) 2π

alterando este para
1.170704 = -6,2831853|5559
passou o valor

1.170704983 = -6,2831853033
(071)

Em resumo
2 ^2.00006 3 ^1.170706 3 ^1.170706 2 ^2.00006
= -6,2831853555
(071).

2 ^2.00006 3 ^1.1707 3 ^1.1707 2 ^2.00006
≃ -6,2831484
(853).

Provisoriamente a equação:

Ⓐ $\left(\frac{2}{1.1284}\right)$ ^ 2.00006 −

Ⓑ $\left(\frac{3}{1.1284}\right)$ ^ 1.1707 −

$$\frac{\pi}{\sqrt{9.7}} - \frac{\pi}{\sqrt{9.8}} = 0,005159648\ldots$$

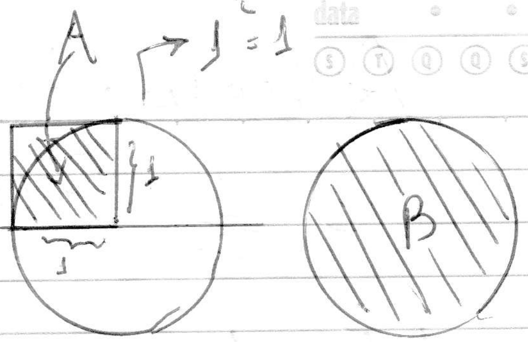
Interessante:

$$\left(\frac{\pi}{\sqrt{2}}\right) - \left(\frac{\pi}{\sqrt{3}}\right) \times 7,706742 \cong$$

$$3,141592\underline{5}$$

(6)

$\sqrt{2} \cong \frac{10}{7}$



Analisando:

$\frac{10}{7} = 1,\overline{428571}$

$\frac{1}{7} = 0,\overline{142857}$

obs:

$\frac{10}{7} \div \frac{1}{7} = \frac{10}{(X \text{ vezes})}$

$A \times 3\frac{1}{7} = B$

$\Downarrow$

$3 + (1/7.06251331)$

$\cong 3,1415926535\ldots$

$1^2 = 1$ e se $1^2 = 2$

Portanto:

$2 \times (1,5 + 1/7) = 3,\overline{285714}$

Analisar o erro ou discrepância envolvidos.

Atente-se que $3\frac{1}{7}$ ou $\frac{22}{7} =$

$3,\overline{142857}$

obs: $((1.5 + 1/7)^* 2) - 22/7 =$ ↓ Estudar !!!

$0,142857$ (erro de $\frac{1}{7}$)

Aprofundando:

$3\ \frac{1}{7}$ fazendo uma redução pela metade, teremos?

$1{,}5\ \frac{1}{14} = (14 \times 1{,}5) + 1 = 22$

$\therefore \frac{22}{14}$

$(22/14) \times 2 = 3{,}\overline{142857}$

Corrigindo a página anterior:

$2 \times (1{,}5 + 1/7) = 3{,}\overline{285714}$,

mas o correto é

$\underbrace{2 \times (1{,}5 + 1/14)} = 3{,}\overline{142857}$

Neste caso, se $1^2 = 2$,

portanto, a área de Ⓐ

1 de lado 1 será igual 2.

Continuando:

$$2 \times (1{,}5 + 1/(14)) = 3{,}\overline{142857}$$

Atente-se:

$$\left(\frac{3}{1.5}\right)^{\wedge} 1.5 = 2{,}828427124\ldots$$

$$\cong$$

$$\sqrt{2} \times 2$$

Observamos que:

$$2^{\wedge} 1{,}65149612944 \cong$$

$$3{,}1415926535\ldots \quad (\cong \pi)$$

Veja:

$$\left(2^{\wedge} 1{,}65149612944\right) - \left(\frac{3}{1{,}5}\right)^{\wedge 1{,}5} =$$

$$\underbrace{0{,}313165528\ldots}$$

$$\left(\frac{\pi}{\sqrt{3}}\right) - 2^{\wedge} 1{,}65149612944 - \left(\frac{3}{1{,}5}\right)^{\wedge 1{,}5} =$$

$$1{,}5006338\ldots$$

(checar!!! com mais precisão)

20220601 m Meu aniversário! 53 anos.

⇒ par.

Vejamos:

2,65 ^ 1,1741 − 1,1741 ^ 2,65 =
= 1,609928 (≅ milha ⇒ checar!)

2,65 ^ 1,54 − 1,54 ^ 2,65 =
= 1,3453719...

Obs: Milha: 1609,344 metros
ou
1,609344 Km

Vejamos o erro:

1,609928 — 100
1,609344   x

x = 99,9637...

obs: Este erro existe porque estamos adotando o $\pi \cong 3,14$

---

off:

1 pol = 25,4 mm ou 2,54 cm

1 metro = 39,37 pol (dízima)

1 milha = 1609,344 metros
$\times$ 39,37...

63360 pol.

checando:

OK

1609,344 metros = 160934,4 cm

160934,4 ÷ 2,54 cm ≅ 63360.

Voltando:

$\left(\frac{2}{1.1284}\right)$ $\left(\frac{2}{1.1707}\right)$ | $\left(\frac{2}{1.1741}\right)$ $\left(\frac{2}{1.1746}\right)$

$\left(\frac{3}{1.1284}\right)$ $\left(\frac{3}{1.1707}\right)$ | $\left(\frac{3}{1.1741}\right)$ $\left(\frac{3}{1.1746}\right)$

$\frac{3{,}1415}{(2/1.1284)} = 1{,}7724343$ (exato) $\frac{3{,}1415}{(3/1.1284)} = 1{,}1816228\overline{6}$

$\frac{3{,}1415}{(2/1.1707)} = 1{,}838877025$ (exato) $\frac{3{,}1415}{(3/1.1707)} = 1{,}22591801\overline{6}$

$\frac{3{,}1415}{(2/1.1741)} = 1{,}844217575$ (exato) $\frac{3{,}1415}{(3/1.1741)} = 1{,}22947838\overline{3}$

$\frac{3{,}1415}{(2/1.1746)} = 1{,}84500295$ (exato) $\frac{3{,}1415}{(3/1.1746)} = 1{,}2300019\overline{6}$

$\frac{3{,}1415}{(2/1.1729)} = 1{,}842332675$ (exato) $\frac{3{,}1415}{(3/1.1729)} = 1{,}22822178\overline{3}$

Aprofundando: (deepening)

$\rightarrow 2,65 \wedge 1.1741 = 3,14002409\ldots$

$1.1741 \wedge 2.65 = 1,53009530\ldots$

$\rightarrow \underline{1,54} \wedge 2.65 = 3,140001895\ldots$

$2,65 \wedge 1.54 = 4,48537\ldots$

Juntando-se: (joined)

$\sqrt[2,65]{3,1415} = \underline{1,54}027721\ldots$ $\Uparrow$

obs: 1,5402772187495553538657192795144...

Interessante:

$1,54027 \wedge 2,65 = 3,1414609\ldots$

$1,540277\underset{\text{wrong}}{7} \wedge 2,65 = 3,141502601\ldots$ (passou este valor)

Veja:

$1,5402 \wedge 2,65 = 3,141082\ldots$

Importante:

$\sqrt[2,6586316]{3,1415}$

$= \left(\dfrac{3}{1.1284}\right)$

Calculando:

data
S T Q Q S S D

$$\sqrt[\frac{3}{1.1284}]{3,1415} \rightarrow 2,65\ldots$$

$$= \underbrace{2,6586316908897}5540\ldots$$

$$\sqrt[\frac{3}{1.1284}]{3,1414}$$

$$= \underbrace{2,6586316908997}5540\ldots$$

Valores iguais

checando valores

3,1415 → 2,65863169088975540588
4438142 5027
3,1414 → 2,65863169088975540588
4438142 5027
(iguais)

→ a diferença de valores deverá estar além da casa 50 após a vírgula.

Com o valor $\left(\frac{3}{1.1707}\right)$:

$$\sqrt[\frac{3}{1.1707}]{3,1415}$$
$$= 2,5625694029 21\ldots$$

$$\sqrt[\frac{3}{1.1707}]{3,1414}$$
$$= 2,5625694029 21\ldots$$

Valores iguais

Calculando outros valores:

$$= \sqrt[\boxed{\frac{2}{1.1284}}]{3,1415}$$

$= 1,77242112725\ldots$

$$= \sqrt[\boxed{\frac{2}{1.1284}}]{3,1414}$$

$= 1,77242112725\ldots$

$$= \sqrt[\boxed{\frac{2}{1.1707}}]{3,1415}$$

$= 1,70837960194\ldots$

$$= \sqrt[\boxed{\frac{2}{1,1707}}]{3,1414}$$

$= 1,70837960194\ldots$

Ajustando: (Important)

$$\left(\frac{3}{1.1284}\right) = 2,658631\ldots$$

Voltando:

$$\sqrt[2,65]{3,1415} =$$

$1,540277218\ldots$

Portanto: Valores:

Ⓐ 1,54 ^ 2,65
= 3,14000189...

{ 1,540277218...
{ 2,658631690...

Ⓑ 1,540277 ^ 2,65
= 3,14146098...

Ⓒ 1,540277 ^ 2,65 se você estender o valor passa 3,1415...

Mudando a ordem

1,54 ^ 2,65 → também não dá certo.

Ⓓ 2,65 ^ 1,54 → não dá certo.

Valor certo: (Usando-se estes valores)

1,540277218749555353865719279514 4
= 3,1415
↓
Este número decorre do número $\left(\frac{3}{1.1284}\right)$ que foi utilizado na raiz do número $\sqrt{3.14150}$ (exato), obtendo-se
2,658631690889...

Interessante:

Ⓐ $\sqrt[2,65]{3,1415} = 1,54027721\ldots$

Ⓑ $\sqrt[1.1707]{3,1415} = 2,6585780195\ldots$

Pag. 159 (169) -

Some problems of Diophantine approximation:

The lattice-points of a right-angle triangle.

(Second memoir). Hardy.

Hecke is mainly transcendental

Ostrowski's is entirely elementary.

Obs: Lattice-points

A point at the intersection of two or more grid lines in a point lattice.

↳ A point lattice is a regular spaced array of points.

A lattice is a discrete subgroup

of a Euclidean space.

Ex: $\{a_1 + a_2\sqrt{2}\} \subset \mathbb{R}$.

requires two generators but is not discrete, and is not a lattice!

$$\frac{N'(r)}{N(r)} = \frac{\frac{24}{\pi^2} r^2 + O(r \ln r)}{4 r^2 + O(r)}$$

$$\frac{\frac{6}{\pi^2} + O\left(\frac{\ln r}{r}\right)}{1 + O\left(\frac{1}{r}\right)}$$

$$= \frac{6}{\pi^2}$$

$$\Rightarrow c = (2\pi^2/3)^{1/3} \simeq 1.87$$

Any parallelogram on the lattice in which two opposite side have length 1 has unit area (Hilbert and Cohn-Vossen 1999, pp 33-34).

179° 59' 59.32"

Obs. Fazer os cálculos para ver
quantos arcsec deram.

Vejá se: 1.75 arcsec or 1.98 ± 0.12
or outro valor.

$179^{a}\ 59'\ 59.32''$ (1.75, 1.98 ± 0.12)

Obj: Estudo

18 arcsec = 0.005°

1 arcsec = $\frac{1}{1.296.000}$ círculo (360°)

$\swarrow$

$\Rightarrow \underbrace{60' \times 60''} \times 360° = 1296000$

Important:

1° = $\underline{3600}$ arcsec

$\therefore$ 1 arc = $0{,}0002\overline{7}$ °

Voltando:

1 arcsec = $\frac{1^{\circ}}{3600}$

Obs: Veja também: milliarcsecond (MAS)
microarcsecond (μAS)

Vejamos:

$1'' = \frac{1}{1296000} \div 100 = \frac{1}{129.6\underbrace{00000}_{(5)}}$

Portanto: $0{,}\underbrace{00000}_{(5)}2\overline{7}$

$59.32'' \rightarrow 0{,}68''$ (20220605)

~~59/60~~ $\frac{5932}{3600}$ (conversão) $\frac{0{,}68}{3600}$ (graus decimais)

$1{,}64\bar{7}$

$\boxed{= 0.0001\bar{8}}$ ↳ graus decimais

Corrigindo:

$179^\circ 59' 59.32'' \rightarrow 59{,}32/3600 = 0{,}01647^\circ$

$59 / 60 = 0{,}98\bar{3}^\circ$

$179^\circ + 0{,}983^\circ + 0{,}01647^\circ =$ ~~180,1477~~° (?)

achei estranho!

Correto é:

$179{,}99947^\circ$

Mais preciso:

$179 + (59/60) + (59{,}32/3600) =$

$179{,}9998\bar{1}$

Diferença:

$$\boxed{\begin{array}{r} 180 \\ -\ 179.9998\bar{1} \\ \hline 0.0001\bar{8} \end{array}}^\circ \rightarrow \text{correto}$$

~~x 60 = 0,011$\bar{3}$~~

~~x 3600 = 0,68~~

$\times 60 = 0{,}011\bar{3}$

$\times 3600 = 0{,}68''$ (OK) → correto

Einstein → Deflection of light by the Sun's Gravitational Field.

Source: Data-NovoVivo-012-2022/Books-012-2022/20220604/Eclipse-1919-Sobral-Einstein/rsnr.2020.0040.pdf

Pág. 07 – The Sobral-4-inch plates gave the most precise and accurate results whith the derived result for light bending, corrected to the limb of the Sun, of 1,98 ± 0,12 arcsec. The error quoted is the probable error. Converting to the now common standard deviation gives 1.98 ± 0.18 arcsec.

Na música → quinta justa: razão 3:2

A matemática foi descoberta ou inventada?

Para mim, a matemática foi descoberta, mas os matemáticos inventaram a forma como ela é descrita.

Wigner (Eugene Wigner) físico abordou os números complexos em um influente ensaio de 1960 chamado:
"The unreasonable effectiveness of mathematics in the physical sciences" (A eficiência irracional da matemática nas ciências naturais).

→ para Wigner → texto originalmente publicado em 1930
Outra fonte: 1960 (ISBN 978-88-459-7946-0)
Italian language

Wigner chega à conclusão de que não se sabe porque a matemática é tão eficiente.
Muitos matemáticos pensam que eles inventaram a matemática.
(eu não acho !!!).

Einstein disse:

"Quanto mais se referem à realidade, mais incertas as leis matemáticas se tornam, e quanto mais precisas elas são, menos se referem à realidade"!

→ referindo-se como é difícil fazer com que as leis da matemática coincidam com as leis da realidade física.

—

"Deusa" egípcia da matemática → Seshat.

—

teoria das categorias

"matemática da matemática"

→ tenta construir pontes entre diferentes áreas da matemática.

—

A realidade física é matemática.

—

Teoria das Cordas

→ é finita.

A teoria é chamada de "cordas" porque o movimento vibratório de uma dessas partículas (subatômicas) é o mesmo de uma corda num instrumento musical como uma harpa ou um violão.

Se colocarmos alguma energia sobre ela, ela vibra.

Obs: Pitágoras → estudo das cordas musicais.

O grande matemático grego pensou que deveria haver um princípio unificador, um paradigma para resumir a vasta criação que vemos ao nosso redor no Universo.

—

Tesla disse: "Tudo é energia".

—

matéria escura com base nesta teoria, seria composta de cordas que vibram em oitavas mais altas.

"O Universo é mais simples do que pensávamos"

—

A matemática sempre
existiu,
os matemáticos apenas
descobriram a
matemática
e inventaram a forma
como a matemática
seria descrita e
apresentada para toda
a humanidade.

Stenio Musich
202206041452

Teoria da Relatividade.

Para mim, a teoria da relatividade fundamentou-se em conceitos de outros pesquisadores como: Poincaré
Maxwell
Lorentz

Devemos observar que a hipótese de Albert Einstein ~~não~~ apresenta uma referência exaustiva de sua fonte bibliográfica.

Einstein disse: "O problema concebido pela minha mente foi respondido pelo luminoso céu do Brasil" 1925.

'Einstein não concebeu este problema, ele apenas descobriu o que acontece no Universo há bilhões de anos.

Stenio Musich
202206041459

Explicação:

As estrelas sempre desviaram a luz e Einstein apenas descobriu o que já estava acontecendo no Universo.

Eu não tiro o seu mérito, mas falar que a sua mente concebeu este problema (Light Deflection) não é uma afirmação perfeitamente correta.

Obs: Edgar Alan Poe
(1809-1849)

→ ensaio "Eureka"
⇒ expressão célebre atribuída a Arquimedes.

Publicação: 1848

Poema em prosa.

→ tipo de um ensaio cosmogônico.

Foi dedicado a
Alexander von Humboldt
(1769-1859)

Poe elogia a sua obra por suas tentativas de descobrir o Universo.

Naquela época os físicos diziam que o Universo era estático, infinito, mecânico e eterno
enquanto que Poe, apresenta o Universo como sendo

{a) dinâmico
b) constante evolução

Na sua introdução, Poe disse

Desejo falar do físico, metafísico e matemático – do universo material e espiritual – de sua essência, sua origem, sua criação, sua condição atual e seu destino.

Em resumo:

a) Big Bang → explosão

Obs: Para mim este aspecto não é tão revolucionário, mas inovador pelo momento em que Poe vivia.

Faça-se a luz → Gênesis (Bíblia)

↳ refere-se ao nosso Universo.

O nosso Universo se expande pois há um vazio que sempre existiu e que permite que o Universo se expanda.

Coincidentemente a teoria do Big Bang começou a tomar forma pelos físico e clérigo belga Georges Lemaître e desenvolvida pelo físico ucraniano George Gamow em 1948.

b) Big Crunch e o modelo do Universo oscilante.

Parte do pressuposto, que a força

da gravidade

fará com que todo o Universo se contraia e colapse sobre si mesmo em uma nova partícula primordial.

⇒ ciclo constante de expansão e contração

Universo Oscilante.

c) Paradoxo de Olbers

Problema levantado pelo astrônomo alemão Heinrich Olbers em 1823.

Por que o céu é escuro? se o Universo é infinito e as estrelas também.

Físico Paul Halpern (USA, 1961) Professor de física da Universidade da Filadélfia, escreveu vários artigos publicados na revista AEAON e na plataforma Medium.

Solução de Poe ⇒

Poe disse:

Se a sucessão de estrelas fosse infinita, então o fundo do céu nos apresentaria uma luminosidade uniforme, como aquela mostrada pela Galáxia — já que não poderia haver absolutamente nenhum ponto, em todo esse pano de fundo, no qual não existiria uma estrela.

Poe foi o primeiro a sugerir que é impossível para nós conseguir ver todo o Universo, que nem sempre esteve ali, e que a luz das estrelas pode levar vários anos (bilhões de anos) para chegar até nós.

Importante: Ⓐ

Para mim, o céu é escuro pois a escuridão decorre do espaço vazio existente que abarca todo o Universo.

Sem este espaço vazio, o Universo não poderia se expandir e evoluir.

Livro: "A Escuridão da Noite: Um Enigma do Universo"

Astrônomo Edward Harrison
(1987)

d) Teoria da relatividade,
multiverso e
buracos negros.

Poe aborda a noção de que
"espaço e duração são um só!"

obs: Alguns autores veem
como uma profetização
do
"espaço-tempo" relativista,
e reflete sobre a intercambialidade
da matéria e da energia.

Poe sugere que nosso Universo
poderia ser um dos muitos que
existem em um plano
infinito.
(≅ multiversos)

Important:

Em um conto anterior,
"Uma descida ao Maelström",
Poe descreve um redemoinho,
um vórtice mortal para

onde objetos são arrastados sem
deixar vestígios.

Interessante:

Tanto Einstein quanto Freud
disseram que
Edgar Allan Poe
era um "caso patológico"!

Obs: Marie Bonaparte,
sobrinha-neta de Napoleão
e discípula de Sigmund Freud,
escreveu uma biografia na qual
analisa psicologicamente o
autor americano com base em
Eureka e no restante de suas
obras.

No prefácio, escrito por Freud,
ele trata Poe como um caso
patológico, algo que Albert
Einstein também disse na
sua época.

Obs: Uma afirmação bem
conveniente para
alguém que utilizou
as idéias de um "louco"
(grifo nosso).

Defensor de Poe: astrônomo
Alberto Coppi (Itália, 1962) de

Observatório Astronômico de Bolonha.

Obs: Vejá carta para a sua sogra de 07 Julho de 1849

⇒ Não tenho vontade de viver desde que fiz Eureka. Não consegui fazer mais nada.

Obs: Esta carta foi escrita 3 meses antes de falecer.

Voltando: Teoria da Relatividade

Einstein ousou questionar a Lei da Gravitação Universal de Isaac Newton.

Obs: Para mim, a gravidade como uma força física fundamental não existe, esta força decorre das demais leis fundamentais da física.

{ Eletromagnetismo
Força Forte
Força Fraca

"As ideias de Newton sempre terão a importância de serem a base sobre a qual nossa concepção moderna da física foi construída"

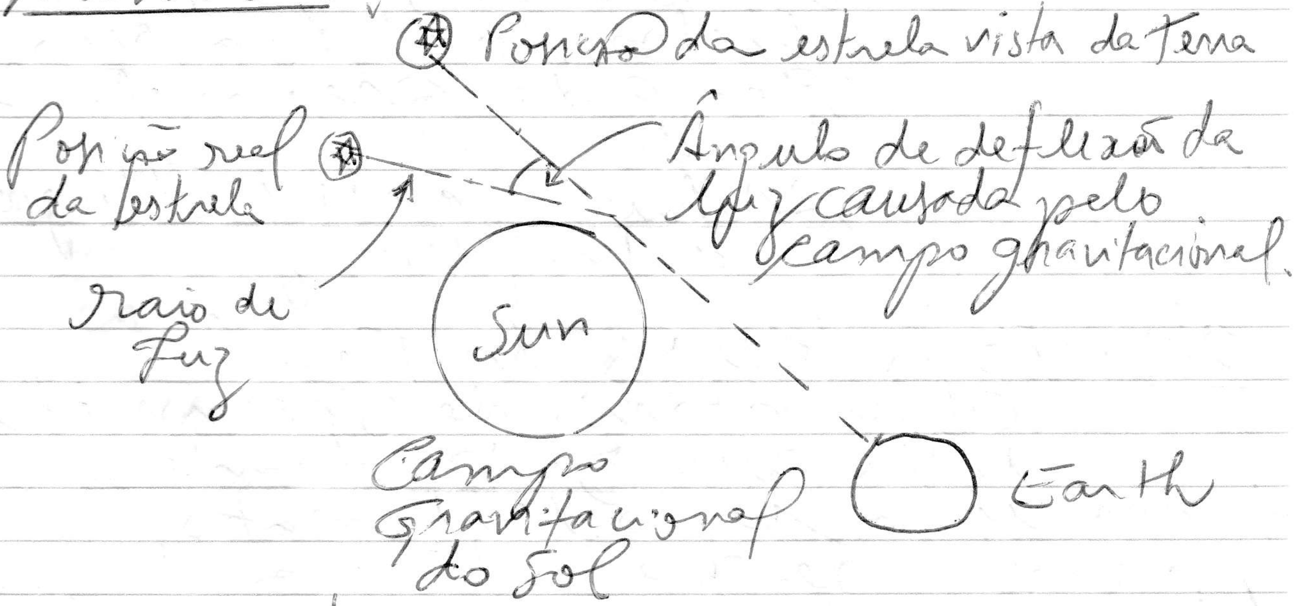
Einstein, 1919.

Livro: "No Shadow of a Doubt)

→ eclipse 1919

Author: Daniel Kennefick.

→ Cálculos de Einstein previam um desvio da luz duas vezes maior do que o que era previsto de acordo com a teoria de Newton



Posição da estrela vista da Terra
Posição real da estrela
Ângulo de deflexão da luz causada pelo campo gravitacional.
raio de luz
Sun
Campo gravitacional do Sol
Earth

Obs: Einstein chegou a investir suas próprias economias na expedição

do astrônomo alemão
Erwin Finlay-Freundlich
para observar um eclipse na
Criméia, na Rússia, em
1914, um ano antes de
publicar a teoria
da relatividade geral.

Freundlich chegou à Rússia,
quando explodiu a Primeira
Guerra. Os seus instrumentos
foram confiscados e ele não
conseguiu realizar o
experimento.

1917 Frank Watson Dyson
astrônomo inglês,
diretor do Observatório
Real de Greenwhich
e
Arthur Stanley Eddington
astrofísico

Obs: Tom Kerss do Real
Observatório de Greenwich,
disse que Dyson também
tinha um certo sentimento
patriótico de que a teoria de
Isaac Newton (que era inglês)
deveria ser tratada com mais
respeito do que a de um jovem

da Alegrante.

Eddington era um entusiasta dos teorias de Einstein e um internacionalista, que acreditava no ideal de juntar as melhores mentes de todas as nacionalidades em busca da verdade científica.

Eles usaram um aglomerado de estrelas especialmente brilhantes, as Híades
→ o Sol estaria perto. (1919)

Duração do eclipse:

5 min 13 → Sobral
5 min 02 → Ilha de Príncipe.

Interessante:

A faixa de totalidade do eclipse, ou seja, o trecho em que o Sol estará completamente encoberto — cruzaria toda a América do Sul, começando na Bolívia passaria pelo Oceano Atlântico e terminaria no continente africano, na Tanzânia.

Obs: Observe que o formato da Lua Quarto Crescente no hemisfério Norte parece um C e no hemisfério

Sol parece um D.
Ela é vista ao contrário, porque a Terra gira de
Oeste para Leste,
portanto, no hemisfério Sul gira no sentido horário e no hemisfério Norte gira no sentido anti-horário.

Decisão de ir a Sobral;

Dyson recebeu uma carta do engenheiro
Henri Charles Morize,
diretor do Observatório Nacional do Rio de Janeiro e um dos fundadores da Academia Brasileira de Ciência (ABC).

Ele informou que Sobral, a segunda maior cidade do Ceará, bem conectada por trens e por um porto relativamente próximo — seria o melhor lugar para acompanhar o fenômeno.

Dyson teve que ficar na Inglaterra, mas enviou
— Charles Davidson, calculista sem formação acadêmica,

mas com muita experiência em telescópios, e

o astrônomo irlandês

Andrew Crommelin,

que operaria um segundo telescópio levado por segurança.

telescópio irlandês é que fez as imagens dos resultados que fizeram história

Tinha o campo visual maior que permitia ver mais estrelas!
foi construído para o eclipse de 1900, era menor e mais velho.

Em novembro de 1918, o Armistício de Compiègne anunciou o fim da guerra e abriu caminho para a expedição.

Eles vieram para o Brasil, Pará, a bordo do Anselm (navio)

Belém Pará para o Ceará no navio CAMOCIM e de trem para Sobral.

Fotos: 29 MAIO 1919

Os astrônomos tiveram cerca de

jandaia

4 minutos para fazer 27 fotos do céu, mostrando as 12 estrelas que queriam observar.

Devido ao calor que dilatou o espelho do seu principal telescópio, as imagens ficaram distorcidas, mas 8 imagens nítidas foram feitas do sol escurecido.

1 mês depois, eles fotografaram as mesmas estrelas, exatamente no mesmo lugar do céu, só que à noite.

2) Gravitational starlight deflection measurement during the 21 August 2017 total (eclipse) solar eclipse.
Published 06 March 2018
IOP Publishing Ltd
Source: https://iopscience.iop.org/

10.1088/1361-6382/aaaf2a/meta

Abstract:

Precise star positions near the Sun were measuring during the 21 August 2017 total solar eclipse in order to measure their gravitational deflections.

The equipment, procedures and analysis are described in detail.

A portable refractor, a CCD camera and a computerized mount were set up in Wyoming.

Detailed calibrations were necessary to improve accuracy and precision.

Nighttime measurements taken just before the eclipse provided CUBIC OPTICAL DISTORTION CORRECTIONS.

Calibrations based on star field images 7,4° on both sides of the Sun taken during totality gave linear and quadratic plate constants.

A total of 45 images of the sky surrounding the Sun were acquired during the middle part of totality, with an integrated exposure of 22 s.

The deflection analysis depended on accurate star positions from the USNO's UCAC5 star catalog.

The final result was a deflection coefficient L = 1.7512 arcsec, in perfect agreement with the theoretical value, with an uncertainty of only 3%

IMPORTANT:

DEFLECTION COEFFICIENT

$$\boxed{L = 1.7512 \text{ arcsec}}$$

Estudo:

$1° = 3600$ arcsec $\therefore 1/3600 = 0{,}0002\bar{7}\,°$ (graus)

$1 \text{ arcsec} = 0{,}0002\bar{7}\,°$

$1{,}7512 \times \left(\frac{1}{3600}\right) = 0{,}000486\bar{4}\,°$

Comparação:

Gauss $\rightarrow 179° \, 59' \, 59.32''$

$179° \, 59' \, 59.32''$

$\rightarrow 59.32/3600 = 0.0164\bar{7}$

$\rightarrow 59/60 = 0.98\bar{3}$

Portanto:

$179° + 0{,}98\bar{3} + 0.0164\bar{7} =$

$179 + (59/60) + (59.32/3600) =$

179,99981

$$\begin{array}{r} 180 \\ -\ \underline{179.99981} \\ 0.00018 \end{array}$$

$0.00018°$
$\times 3600 =$

Equation:

$(180-(179+(59/60)+(59{,}32/3600)=0.00018''$ ✡

$\times 3600 = 0{,}68''$ (exato)

Portanto: Equation

$3600 * (180-(179+(59/60)+(59{,}32/3600)=$
$0{,}68''$

Análise:

a) Deflection Coefficiente (2017)

$\angle = 1{,}7512$ arc sec $=$

$1{,}7512 \times \left(\frac{1}{3600}\right) =$

$0{,}000486\bar{4}°$

b) Gauss − curvature (space)

$179°59'59{,}32''$ or 179.99981

desvio $0.00018°$ decimais (graus decimais).

Fazendo as equações:

Diferença:

① $1,7512 \times \left(\frac{1}{3600}\right) = 0.0004864°$

② $179 + (59/60) + (59.32/3600) = 0.00018°$

Portanto:

$1,7512 \times \left(\frac{1}{3600}\right) - (179 + (59/60) + (59.32/3600) =$

$0,000297\bar{5}°$

⇘ 2 cont.)

Pág. 136(144) 6.3

Geodesics of Schwarzschild: Gravitational Redshift, Perihelion Precession, Bending of Light, and Time Delay of Radar Signals

Pag. 142(150) → (For the Kerr metric with a=M, the corresponding fraction of energy radiated is 42%.)

Pag. 144(152) -

Schwarzschild geometry will capture any photon sent toward it with an apparent impact parameter smaller than the critical value, b_c, given by

$$b_c = 3^{3/2} M \qquad (6.3.33)$$

Hence, the capture cross section, σ, for photon is the Schwarzschild geometry is

$$\sigma = \pi b_c^2 = 27 \pi M^2 \qquad (6.3.34)$$

IMPORTANT:

"Light Bending" ⟹

To analyze the "light bending" effects of the

Schwarzschild geometry

On the light rays which are not captured, it is convenient to derive an equation for the spatial orbit of the light ray by solving equation (6.3.14) for $\dot{r}$ and...

obs.:

(6.3.14) ⇒ we obtain our final equation for geodesics with remarkably little labor,

$$\frac{1}{2}\dot{r}^2 + \frac{1}{2}\left(1 - \frac{2M}{r}\right)\left(\frac{L^2}{r^2} + K\right) = \frac{1}{2}E^2$$

... then dividing $\dot{\phi}$, equation (6.3.13), by $\dot{r}$. We obtain

$$\frac{d\phi}{dr} = \frac{L}{r^2}\left[E^2 - \frac{L^2}{r^3}(r-2M)\right]^{-1/2} \qquad (6.3.35)$$

We wish to find the change,

$\Delta\phi = \phi_{+\infty} - \phi_{-\infty}$, in the angular coordinate ϕ of a light ray in the Schwarzschild geometry traversing a path as illustrated in Fig 6.6-1

Pág. 196(200) - 258. El número π.

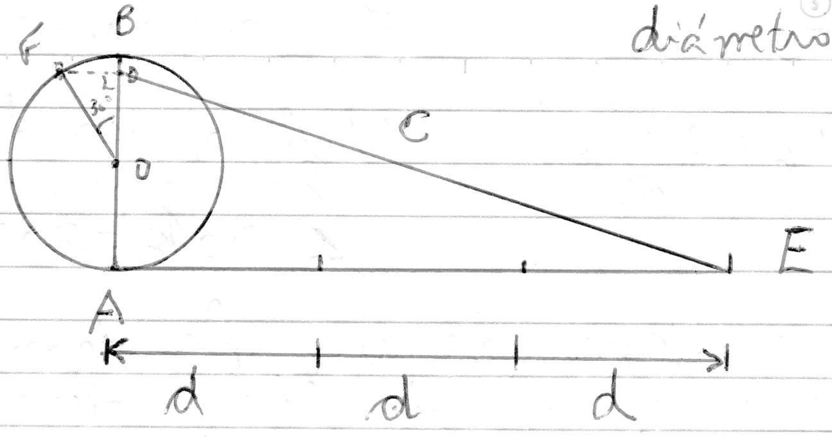
Pág. 198(202) - 263. Método Gráfico para rectificar aproximadamente una circunferencia.

Rectificar una circunferencia es obtener un segmento rectilíneo (raya) cuya longitud sea igual a la de la curva.

1) Tracemos un diámetro $\overline{AB}$ (Fig. 221)
2) Por A, tracemos la tangente.
3) Sobre dicha tangente y a partir de A tomemos tres diámetros. Se obtiene el punto E.

Fig. 221 →

diámetro = 2,7 cm



4) Tracemos ∠ BOF = 30°.

5) Bajemos $\overline{FD} \perp \overline{OB}$.

6) Unamos D con E. $\overline{DE}$ es la solución del problema.

264. Justificación de la construcción anterior.

En el Δ AED:

$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AD})^2$ (1) Teorema de Pitágoras

Pero:

$\overline{AD} = \overline{AO} + \overline{OD}$ (2) Suma de segmentos.

Substituyendo (2) en (1), tenemos:

$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AO} + \overline{OD})^2$ (3)

Pero:

$\overline{EA} = 3d = 6r$ (4) Construcción;

$\overline{AO} = r$ (5) Construcción;

$\overline{OD} = a_6 = \frac{r\sqrt{3}}{2}$ (6) Apotema de um hexágono inscrito; $\angle DOF = 30°$

Obs: O apótema de um hexágono é o comprimento da linha que une o centro do hexágono com o centro de um lado.

O apótema é a linha perpendicular que coneta (conecta) o centro do hexágono com um lado.

Substituyendo (4), (5) y (6), en (3), tenemos:

$$(DE)^2 = (6r)^2 + \left[r + \frac{r\sqrt{3}}{2}\right]^2 =$$

$$= 36r^2 + r^2 + r^2\sqrt{3} + \frac{3r^2}{4}$$

$$= r^2(36+1)\sqrt{3} + \frac{3}{4}$$ Sacando r^2 en factor común;

$$= r^2(36 + 1 + 1.73 + 0.75)$$

$$= r^2(39.48)$$

$$= 39.48r^2$$

$\therefore$

$$\overline{DE}^2 = \sqrt{39.48 r^2}$$

$$= \sqrt{39.48}\, r$$

$$= 6.28\, r$$

$$= 2 \times 3,14 \times r =$$

$$= 2\pi r$$

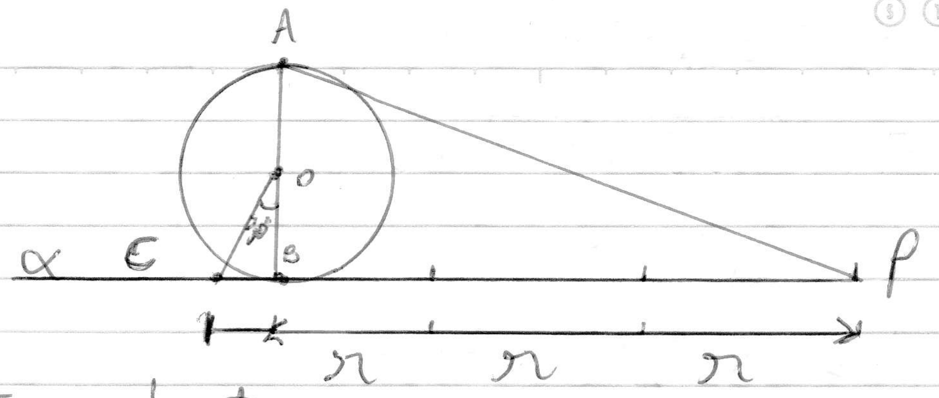
2) Enciclopédia Prática Jackson - Volume X.

Pág. 259 - item 81 (parágrafo 81)

Retificação da circunferência e quadratura do círculo.

Retificação aproximada.

Outra construção diferente da primeira figura (construção), mas que no fundo é a mesma coisa (30°), diferenciando onde está o apótema.



Important:

No Ponto C que é a reta $\overline{OC}$ sendo a hipotenusa de um triângulo retângulo ΔCBO.

O ângulo é de 30° mas a reta é projetada até encontrar a reta α no ponto C.

A partir do Centro O traçamos a reta OC formando um ângulo de 30° com o diâmetro AB.

De C e sobre a tangente em B, transportamos 3 vezes o raio

$CP = 3r$.

Unindo A com P obtemos o segmento ~~AB~~ $\overline{AP}$ aproximadamente igual à semicircunferência.

Com efeito: por ser o ângulo de 30° é

$$CB = \frac{CO}{2}$$

Por conseguinte, recordando o dito para os triângulos equiláteros, temos:

$$CO = \frac{2r}{\sqrt{3}} \quad e \quad CB = \frac{r}{\sqrt{3}}$$

Então:

$$\overline{BP} = \overline{CP} - \overline{CB} = 3r - \frac{r}{\sqrt{3}} =$$

$$= r\left(3 - \frac{\sqrt{3}}{3}\right)$$

Visto que após a multiplicação do numerador e do denominador por $\sqrt{3}$,

$\frac{1}{\sqrt{3}}$ converte-se em $\frac{\sqrt{3}}{3}$

Logo, pelo teorema de Pitágoras, temos:

$$AP^2 = AB^2 + BP^2 =$$

$$= 4r^2 + r^2\left(\frac{28}{3} - 2\sqrt{3}\right) =$$

$$= r^2(40 - 6\sqrt{3}) : 3$$

E, efetuando as operações:

$AP = 3,14153\, r$

e como o semiperímetro da circunferência (ver parágrafo 82) é

$1 = \pi r = 3,1415\, r$

o erro que cometemos nesta construção é de 0,00006 . r, ou seja, 0,002%

---

C
Ponto de Deflexão da Luz.
60°
a
a
h
triângulo equilátero
60°
60°
A
M
B

ABC → triângulo equilátero

Se o comprimento do lado é a, a altura h pode ser calculada por meio do Teorema de Pitágoras.
Visto que no triângulo retângulo AMC, é $AM = \frac{a}{2}$, $AC = a$, verificamos:

$$h^2 = a^2 - \left(\frac{a}{2}\right)^2 = \frac{3}{4}a^2$$

Donde $h = a\frac{\sqrt{3}}{2}$

Se conhecemos a altura h, o lado será

$$a = h\,\frac{2}{\sqrt{3}}$$

Exemplo: Se $a = 1$ m temos

$$h = \frac{\sqrt{3}}{2}\,m = 0{,}8666 = 1 \text{ vara}$$

Obs.: Com efeito, este é o valor adotado para a vara argentina, a qual tem sobre as diversas varas européias a vantagem de ser muito simples com relação a áreas:

$$1\,v^2 = \frac{3}{4}\,m^2 = 75\,dm^2$$

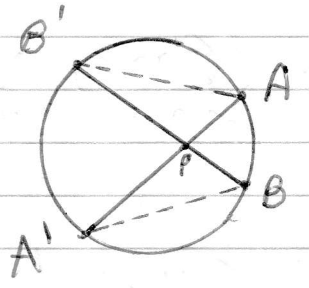
$$1\,m^2 = \frac{4}{3}\,v^2$$

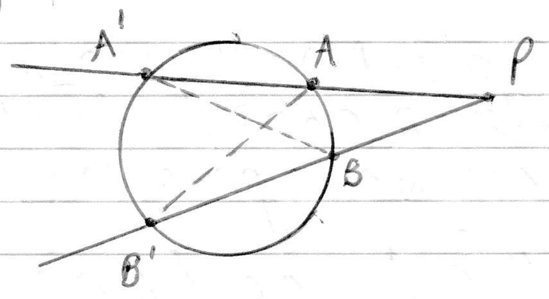
Para reduzir um número de varas quadradas a metros, subtraímos-lhes sua quarta parte; para reduzir metros quadrados a varas somamos-lhes a terça parte.

Generalizando: a altura de um triângulo equilátero mede em varas, o que o lado mede em metros.

Exercício: No hexágono regular, o apótema mede em varas o que o lado mede em metros.

4) Jackson - Pág. 257





6. Se de um ponto P interior ou exterior a uma circunferência traçarmos as secantes A A' e B B' verificamos sempre

$$PA \cdot PA' = PB \cdot PB'$$

e esse produto constante é a potência do ponto P em relação à circunferência.

(Unindo A com B' e

A' com B

formam-se os triângulos PAB' e PA'B que têm os ângulos iguais (veja o parágrafo 35, exercício 5) e da proporcionalidade dos lados tiramos a importante igualdade enunciada).

22.1 - From Topological Surfaces

to Riemann Surfaces.

There are several natural additional structures one may place on a topological surface Σg.

(1) The first is a Riemannian metric (see Sec. 1.4.1), given by a positive definite symmetric two tensor

$$g_{ij}\, dx^i \otimes dx^j.$$

This gives a notion of distance on the surface.

Obs.: Pág. 12 (33) - 1.4.1

Metric on Manifolds

(2) A conformal structure is given by the data of a Riemannian metric up to multiplication by a (positive) function on Σg.

A conformal structure determines angles between tangent vector of Σg.

Two Riemannian metrics giving the same conformal structure are said to be conformally equivalent.

(3) An almost complex structure is an automorphism of the tangent bundle $J: T\Sigma g \to T\Sigma g$

such that $J^2 = -1$.

Every conformal structure determines a canonical almost complex structure:

J is defined by counter-clockwise rotation by 90 degrees.

An almost complex structure gives the fibers of $T\Sigma_g$ the structure of a one-dimensional complex vector space, where J is interpreted as multiplication by i.

Thus there is a canonical correspondence between the set of conformal structures on Σ_g and the set of almost complex structures.

(4) An almost complex structure is *integrable* if there exist holomorphic charts for Σ_g.

Every almost complex structure on a surface is *integrable* - this is a *deep theorem in complex analysis* (analysis).

A surface Σ_g with a (given) complex structure (an integrable almost complex structure) is called a

non-singular complex curve or Riemann surface.

(5) Finally, every Riemann Surface is algebraic - it can be described as the vanishing set of polynomials in $\mathbb{C}\mathbb{P}^m$ and may be studied using algebro-geometric tools (see ch. 2).

Obs Theorem 22.1.1

(Riemann-Roch)

Suppose V is a rank r vector bundle on a Riemann surface Σ_g. then:

$$h^0(\Sigma_g, V) - h^1(\Sigma_g, V) =$$
$$\deg c_1(V) + r(1-g).$$

Note that all higher cohomology groups of V vanish, by the dimensional vanishing Σ_g (21.1)

This is a special case of the Grothendieck-Riemann-Roch-formula, see Sec 3.5.3. (Pág. 52 (73)).

Lectures on Quaternions -
Hodges and Smith (1853).pdf ⇙

Pag. 318(457) - item 332

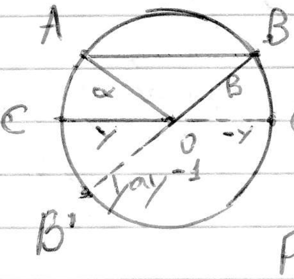

Fig. 71

Consider for this purpose any two radii OA, OB, of a circle (a great circle of the sphere), and draw, as in the annexed figure 71, the diameter COC' parallel to the chord AB; draw also the diameter BOB';

and let it be reqeired (required) to express OB, or its opposite OB' by means of OA and OC (or OC').

Here, because a canonical rotation through two right angles, round either OC or OC' as an axis, would bring the radius OA into the position OB' it results from the present Lecture (arts. 290, 291) that this radius OB' may be expressed as follow:

$OB' = OC \times OA \div OC =$

$OC' \times OA \div OC'$.

But OB is opposite to OB'; wherefore

$OB = -OC \times OA \div OC =$

$-OC' \times OA \div OC'$.

Or writing for conciseness,

$OA = \alpha, \ OB = \beta, \ OC = \gamma,$

the expression for β as a function of α and γ is found to be:

$$\beta = -\gamma \alpha \gamma^{-1}.$$

Obs. arts. 290 e 291 —

Pág. 275(414) e Pág. 276(415), respectivamente.

Art. 290 — If the operating quaternion q reduce itself to a vector, suppose γ, then since its double angle is equal to two right angles, or in symbols,

$\boxed{2 \angle \gamma = \pi}$, ⟸ estudar!!!

the operation symbolized by

$$\gamma(\ )\gamma^{-1}$$

is seen to have the effect of simply REFLECTING the vector or body on which it operates, with respect to the operating vector, γ.

That is to say this operation causes each operand vector,

$T\alpha$

suppose ρ, drawn from the common origin O, to turn conically through (através) two right angles round the line γ, which is here conceived to be drawn from the same origin. and thereby (deste modo) brings this operand ρ, without change of length into a new position ρ' such that while (tal que enquanto) we have the equation between tensors,

$T\rho' = T\rho$, if $\rho' = \gamma\rho\gamma^{-1}$,
the line $\pm\gamma$ at the same time bisects the angle between ρ and ρ': and consequently the following equation between versors also holds good:

$$U.\rho'\gamma^{-1} = U.\gamma\rho^{-1}.$$

For example, in fig. 40, → Pág. 218 (357)

$$\gamma\epsilon\gamma^{-1} = \delta;$$

also, in same figure,

$$\beta\zeta\beta^{-1} = \delta, \text{ and}$$

$$\alpha\epsilon\alpha^{-1} = \alpha^{-1}\epsilon\alpha = \zeta.$$

Art. 291 (Pág. 276 (415)).

Another mode of interpreting the symbol

$$\gamma\rho\gamma^{-1}$$

is the following. We may observe that, by 111, 117,

$$\rho = -\rho^{-1}T\rho^2;\ \gamma^{-1} = -\gamma T\gamma^{-2};$$

and that therefore

$$\gamma\rho\gamma^{-1} = T\rho^2\, T\gamma^{-2} . \underbrace{\gamma\rho^{-1}\gamma}_{};$$

(133, 194) ⇔ denotes the third proportional to the two vectors ρ and γ;

and therefore that (see 134) the vector $\pm\gamma$ bisects the angle between the directions of ρ and $\gamma\rho^{-1}\gamma$;

or by the recent transformation, the angle between ρ and $\gamma\rho\gamma^{-1}$: which was the graphic part of the result of the last article.

And with respect to the METRIC part of that result, we know (by 129, &c) that the tensor of a third proportional is the third proportional to the tensors, and therefore that

$$T . \gamma\rho^{-1}\gamma = T\gamma^2 . T\rho^{-1};$$

an expression which reduces itself to $T\rho$, when it is multiplied by $T\rho^2$, and divided by $T\gamma^2$.

Indeed (De fato) it is clear

from the more general principle
of art. 188, respecting the tensor
of a product that

$$T.\,\gamma\rho\gamma^{-1} = T\gamma\, T\rho\, T\gamma^{-1} = T\rho.$$

Item 459 (artigo 459) →
Pág. 458(597).

Apollonius found, and the ancient result has acquired fresh interest in our own days by a remarkable application of to electricity,

that the locus of a point whose (~~de~~ cujos) distances from two given points are in a given ratio of inequality, is (in the plane) a circle.

To investigate this locus by quaternions, let the two given points be

O and A, and the variable point P;

also let the ratio of $\overline{AP}$ to $\overline{OP}$ that of $\underline{\underline{n}}$ to 1, and suppose $n > 1$: then, making $OA = \alpha$ and

$OP = \rho$, the equation

of the locus is,

Jandaia

$T(\rho-\alpha)=nT\rho$, or

$(\rho-\alpha)^2=n^2\rho^2$.

Developing, transposing, etc,
we find successively,

$$(n^2-1)\rho^2+2S.\alpha\rho=\alpha^2,$$

$$\{(n^2-1)\rho+\alpha\}^2=(n^2-1)\alpha^2+\alpha^2=n^2\alpha^2,$$

$$T\{(n^2-1)\rho+\alpha\}=nT\alpha,$$

and finally, $T(\rho-\beta)=c$,
if we make, for abridgment, (em resumo)

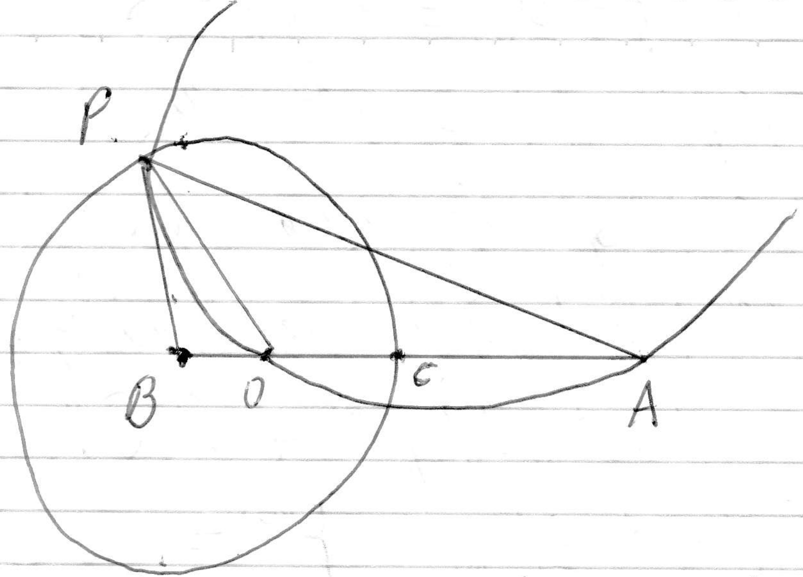
$$\beta=\frac{-\alpha}{n^2-1},$$

$$c=\frac{nT\alpha}{n^2-1},$$ so that

$$\beta-\alpha=n^2\beta,\ c^2=-n^2\beta^2=\beta(\alpha-\beta).$$

Jandaia

Fig. 96



Hence (porismo) follows this construction, which agree to known results.

Cut the given line AO externally at B, in the duplicate of given ratio of the sides, so as to have

$$AB = n^2 OB;$$

take BC a geometrical mean between the segments BO, BA; and with centre B, and radius BC, describe a spheric surface; it will be (in space) the required locus of all the points P, for

Whice $\overline{AP} = n . \overline{OP}$

As a verification, let $C - B = \gamma$,
$P - B = \sigma$; we shall have
$A - B = n\gamma$, $O - B = n^{-1}\gamma$,
$P - A = \sigma - n\gamma$,
$P - O = \sigma - n^{-1}\gamma$; it ought (eu pensei) (it ought to be (deveria ser))
then turn out that (acontece que)

$T(\sigma - n\gamma) = T(n\sigma - \gamma)$, if $T\sigma = T\gamma$;
and accordingly, (adequadamente)
$(\sigma - n\gamma)^2 = (n\sigma - \gamma)^2 = (n^2+1)\gamma^2 - 2nS.\gamma\sigma$,
if $\sigma^2 = \gamma^2$.

It is evident from elementary geometry that the fixed locus of P, constructed as above, cuts perpendicularly the

CIRCLE CIRCUMSCRIBED

about the variable triangle AOP, or that is radius BP is a tangent to this circumscribed circle; and this result also might be confirmed by calculation with quaternions, if we chose to use here the conclusion of art. 198, respecting the construction by a tangential vector, of the continued product of the three sides of a triangle inscribed in a circle.

Obs: Art. 198 →

Pág. 201 (340)

Points:

(A − C)(C − B)(B − A), or

(B − A)(C − B)(A − C),

for any three points of space A, B, C, supposed at first to be not situated on one straight line, but to be the corners of a plane triangle; namely, as denoting a certain line or vector, whose length represents the product of the lengths of the sides of that triangle, while its direction is that of the tangent at A to the segment ABC, of the circle circumscribed about it.

Important:

Item (23) → Instead of conceiving (concepção)
that the point D, on the line OD,

has been reflected into the position F, or OF, with respect to the point B, or the line OB, with a similar

SUCCESSIVE REFLETION

from F to E, we may conceive that a point has moved along a small semicircle, with B for pole, from D to F, as indicated in Fig. 69, and then along another small semicircle, with A for pole, from F to E;

and we see that the result, or effect, of these two successive and semicircular motions is equivalent to a motion along an arc DE of a third small circle, which is parallel (as before) to the great circle through B and A, and has a projection RS thereon (here also), which (still as before) is double of the given arc BA.

Transforms to $f(ax)$ or $f\left(\frac{x}{a}\right)$; when $f(x)$ Transforms to $f(-x)$, when $f(x)$ Transforms to $-f(x)$

Pág. 207 (218) Example 14

Draw the graph of $y = -\log(x)$, when the graph of $y = \log x$ is known.

Solution: As $y = \log x$ is given, then $y = -\log$ is the image of $\log x$ in the x-axis as plane mirror.

Thus, it can be drawn as show in figure.

Other book:

Laidlaw - Tachyons, Boundary Interactions and Genus Expansion in String theory [thesis] (2003).pdf

Obs.: 148 pages.

The special theory of relativity, applied to tachyons leads to the following paradox.

Using a tachyon telephone a person, A, emits a tachyon to B at a point of time t_1.

B moves away from A.

The tachyon is reflected by B and reach A before it was emitted, see Fig. 2.15.

If the tachyon could carry information it might bring an order to destroy the tachyon emitter when it arrives back at A.

Figure 2.15 -

A emits a tachyons at the point of time t_1. It is reflected by B and arrives at A at a point of time t_2 before t_1.

Note that the arrival event at A is later than the reflection event as measured by B.

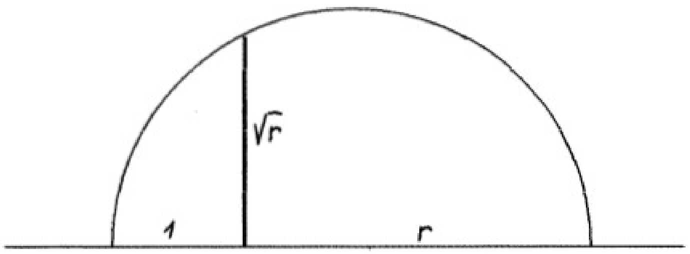
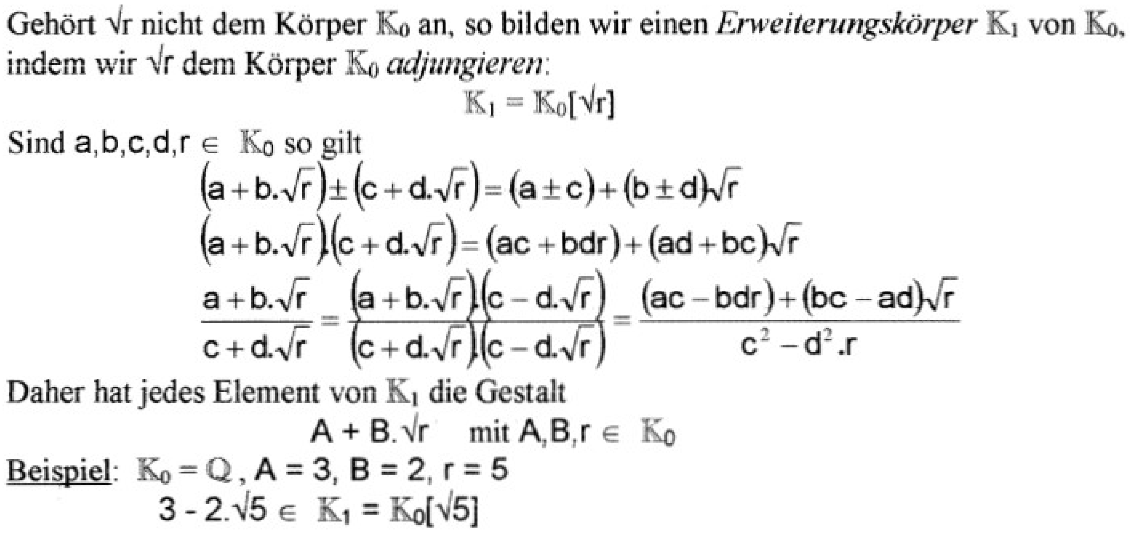
Schnitte von Kreisen und Geraden sowie von Kreisen mit Kreisen führen auf quadratische Gleichungen mit Koeffizienten aus dem Grundkörper $\mathbb{K}_0$. Die Lösung einer quadratischen Gleichung hat die Gestalt

$$a + b.\sqrt{r} \quad \text{mit } a,b,r \in \mathbb{K}_0$$

Die Wurzel $\sqrt{r}$ läßt sich nach dem Höhensatz für das rechtwinkelige Dreieck mit Zirkel und Lineal konstruieren:





Gehört $\sqrt{r}$ nicht dem Körper $\mathbb{K}_0$ an, so bilden wir einen *Erweiterungskörper* $\mathbb{K}_1$ von $\mathbb{K}_0$, indem wir $\sqrt{r}$ dem Körper $\mathbb{K}_0$ *adjungieren*:

$$\mathbb{K}_1 = \mathbb{K}_0[\sqrt{r}]$$

Sind $a,b,c,d,r \in \mathbb{K}_0$ so gilt

$$\left(a + b.\sqrt{r}\right) \pm \left(c + d.\sqrt{r}\right) = \left(a \pm c\right) + \left(b \pm d\right)\sqrt{r}$$

$$\left(a + b.\sqrt{r}\right).\left(c + d.\sqrt{r}\right) = \left(ac + bdr\right) + \left(ad + bc\right)\sqrt{r}$$

$$\frac{a + b.\sqrt{r}}{c + d.\sqrt{r}} = \frac{\left(a + b.\sqrt{r}\right).\left(c - d.\sqrt{r}\right)}{\left(c + d.\sqrt{r}\right).\left(c - d.\sqrt{r}\right)} = \frac{\left(ac - bdr\right) + \left(bc - ad\right)\sqrt{r}}{c^2 - d^2.r}$$

Daher hat jedes Element von $\mathbb{K}_1$ die Gestalt

$$A + B.\sqrt{r} \quad \text{mit } A,B,r \in \mathbb{K}_0$$

Beispiel: $\mathbb{K}_0 = \mathbb{Q}$, $A = 3$, $B = 2$, $r = 5$

$$3 - 2.\sqrt{5} \in \mathbb{K}_1 = \mathbb{K}_0[\sqrt{5}]$$

sense of rotation is preserved, while it is reversed for $\frac{d\mu}{dm} < 0$ Now $ad-bc$ is just the Jacobian determinant

$$\frac{d(\xi,\eta)}{d(x,y)} = \begin{vmatrix} \phi_x & \phi_y \\ \psi_x & \psi_y \end{vmatrix}$$

evaluated at the point P_0. We conclude that the mapping $\xi = \phi(x,y), \eta = \psi(x,y)$ *preserves or reverses orientations near the point* (x_0,y_0) *according to whether the Jacobian determinant at that point is positive or negative.*

10.12 Surfaces

As for curves, in most cases the parametric representation is found suitable for surfaces [5]. Since a surface is a two dimensional object, it requires two parameters to fix a point on it, as against one parameter required to fix a point on a curve. Thus, a parametric representation of a surface is given by parameterizing the position vector $\mathbf{x} \equiv (x,y,z)$ of a point on the surface,

$$\mathbf{x} = \mathbf{\Phi}(u,v) \equiv (x = \phi(u,v), y = \psi(u,v), z = \chi(u,v)) \tag{10.53}$$

where we assume the surface to be smooth, that is, $\mathbf{x} = \mathbf{\Phi}(u,v)$ is a continuously differentiable vector valued function or, equivalently, $x = \phi(u,v)$, $y = \psi(u,v)$, $z = \chi(u,v)$ are continuously differentiable scalar valued functions of two parameters (u,v). The point (u,v) ranges over some region $\mathcal{R}$ in the (u,v) plane. The corresponding point $\mathbf{x}(u,v) \equiv (x = \phi(u,v),\ y = \psi(u,v),\ z = \chi(u,v))$ ranges over a set in $\mathcal{E}_3$ or $\mathbb{R}^3$ spanning the surface. We can describe the surface in one of the three forms $z = f(x,y)$, $y = f(z,x)$, $x = f(y,z)$ by solving one of the three pairs of equations drawn out of $x = \phi(u,v), y = \psi(u,v), z = \chi(u,v)$. Solving any such pair of equations is equivalent to inverting the corresponding $\mathbb{R}^2 \mapsto \mathbb{R}^2$ map, say $(u,v) \mapsto (x = \phi(u,v),\ y = \psi(u,v))$ to express (u,v) as functions of (x,y) which can then be substituted in $z = \chi(u,v)$ to get $z = f(x,y)$. Thus, we require that not all of the three $\mathbb{R}^2 \mapsto \mathbb{R}^2$ maps corresponding to three pairs of equations be non-invertible, that is, we require that the three Jacobian determinants

$$\begin{vmatrix} \psi_u & \psi_v \\ \chi_u & \chi_v \end{vmatrix}, \begin{vmatrix} \chi_u & \chi_v \\ \phi_u & \phi_v \end{vmatrix}, \begin{vmatrix} \phi_u & \phi_v \\ \phi_u & \phi_v \end{vmatrix} \tag{10.54}$$

do not all vanish at once. We can summarize this condition in a single inequality

$$(\phi_u\psi_v - \phi_v\psi_u)^2 + (\psi_u\chi_v - \psi_v\chi_u)^2 + (\chi_u\phi_v - \chi_v\phi_u)^2 > 0 \tag{10.55}$$

If the inequality Eq. (10.55) is satisfied, in some neighbourhood of each point on the surface given by the $\mathbb{R}^2 \mapsto \mathbb{R}^3$ map in Eq. (10.53), it is certainly possible to express one of the three coordinates in terms of the other two.

At each point on the surface with parameters u, v we can partially differentiate the position vector to give

$$\mathbf{x}_u = (\phi_u, \psi_u, \chi_u) \quad \text{and} \quad \mathbf{x}_v = (\phi_v, \psi_v, \chi_v) \tag{10.56}$$

The differential of the vector $\mathbf{x}$ using the corresponding Jacobian, is given by

$$d\mathbf{x} = \begin{pmatrix} dx \\ dy \\ dz \end{pmatrix} = \begin{pmatrix} \phi_u & \phi_v \\ \psi_u & \psi_v \\ \chi_u & \chi_v \end{pmatrix} \begin{pmatrix} du \\ dv \end{pmatrix} = \mathbf{x}_u du + \mathbf{x}_v dv. \tag{10.57}$$

The three determinants Eq. (10.54) are just the components of the vector product $\mathbf{x}_u \times \mathbf{x}_v$. The expression on the left of the inequality in Eq. (10.55) is the square of the length of the vector $\mathbf{x}_u \times \mathbf{x}_v$ so that condition Eq. (10.55) is equivalent to

$$\mathbf{x}_u \times \mathbf{x}_v \neq \mathbf{0} \tag{10.58}$$

As an example, the spherical surface $x^2 + y^2 + z^2 = r^2$ of radius r is represented parametrically by the equations

$$x = r\cos u \sin v,\ \ y = r\sin u \sin v\ \ z = r\cos v,\ \ (0 \leq u < 2\pi,\ 0 \leq v \leq \pi) \tag{10.59}$$

where $v = \theta$ is the "polar inclination" or the polar angle and $u = \phi$ is the "longitude" or the azimuthal angle made by the point on the sphere. Note that the functions relating x, y, z to u, v are single valued and cover all the sphere. As v runs from $\pi/2$ to π the point x, y, z spans the lower hemisphere, that is,

$$z = -\sqrt{r^2 - x^2 - y^2}$$

while the values of v from 0 to $\pi/2$ give the upper hemisphere. Thus, for the parametric representation it is not necessary, as it is for the representation

$$z = \pm\sqrt{r^2 - x^2 - y^2},$$

to apply two single valued branches of the function in order to span the whole sphere.

We obtain another parametric representation of the sphere by means of *stereographic projection*. In order to project the sphere $x^2 + y^2 + z^2 - r^2 = 0$ stereographically from the north pole $(0, 0, r)$ on the equatorial plane $z = 0$, we join each point of the surface to the north pole N by a straight line and call the intersection of this line with the equatorial plane the *stereographic image* of the corresponding point of the sphere (see Fig. 10.5). We thus obtain a $1-1$ correspondence between the points of the sphere and the points of the plane, except for the north pole N. Using elementary geometry, we find that this correspondence is expressed by

$$x = \frac{2r^2u}{u^2+v^2+r^2},\ y = \frac{2r^2v}{u^2+v^2+r^2},\ z = \frac{(u^2+v^2-r^2)r}{u^2+v^2+r^2}, \tag{10.60}$$

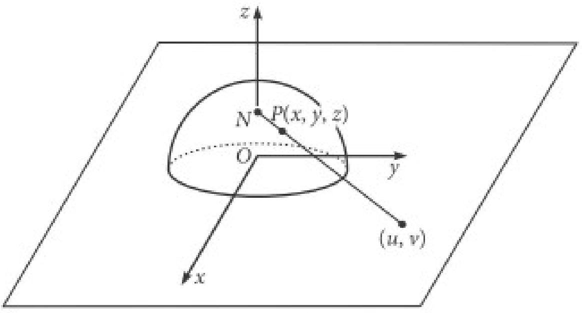

Fig. 10.5 Stereographic projection of the sphere

where (u,v) are the rectangular (cartesian) coordinates of the image point in the plane. These equations can be regarded as the parametric representation of the sphere, the parameters (u,v) being the rectangular coordinates in the u,v (equatorial) plane.

As a further example, we give parametric representation of surfaces

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2}=1 \quad \text{and} \quad \frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2}=-1$$

called the *hyperboloid of one sheet* and the *hyperboloid of two sheets* respectively (see Fig. 10.6). The hyperboloid of one sheet is represented by

$$\begin{aligned} x &= a\cos u\cosh v, \\ y &= b\sin u\cosh v, \\ z &= c\sinh v \end{aligned} \tag{10.61}$$

where $0 \le u < 2\pi$; $-\infty < v < +\infty$ and the hyperboloid of two sheets by

$$\begin{aligned} x &= a\cos u\sinh v, \\ y &= b\sin u\sinh v, \\ z &= \pm c\cosh v \end{aligned} \tag{10.62}$$

where $0 \le u < 2\pi$; $0 < v < +\infty$.

In general, we may regard the *parametric representation* of a surface as the *mapping of the region $\mathcal{R}$ of the (u,v) plane onto the corresponding surface.* To each point of the region

projection. In order to project the sphere $x^2+y^2+z^2-r^2=0$ stereographically from the north pole $(0,0,r)$ on the equatorial plane $z=0$, we join each point of the surface to the north pole N by a straight line and call the intersection of this line with the equatorial plane the *stereographic image* of the corresponding point of the sphere (see Fig. 10.5). We thus obtain a $1-1$ correspondence between the points of the sphere and the points of the plane, except for the north pole N. Using elementary geometry, we find that this correspondence is expressed by

$\mathcal{R}$ of the (u,v) plane there corresponds one point of the surface and typically the converse is also true.[5]

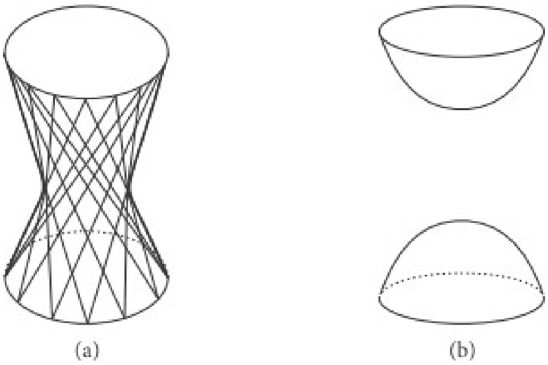

Fig. 10.6 (a) Hyperboloid of one sheet and (b) Hyperboloid of two sheets

Just as we can parameterize a surface by mapping a region in the u,v plane via Eq. (10.53), we can parameterize a curve on a surface by mapping an appropriate curve in the u,v plane onto the given curve on the surface. Thus, a curve $u = u(t)$, $v = v(t)$ in the u,v plane corresponds, by virtue of Eq. (10.53), to the curve

$$\mathbf{x}(t) = \mathbf{\Phi}(u(t),\, v(t)) \equiv (x(t) = \phi(u(t),\, v(t)),\, y(t) = \psi(u(t),\, v(t)),$$
$$z(t) = \chi(u(t), v(t))) \tag{10.63}$$

on the surface. Thus for example, the coordinate lines passing through a point on the sphere have the parametric equations $u = \phi =$ constant (longitudes) and $v = \theta =$ constant (latitudes). Corresponding curves in the u,v plane are the lines parallel to v and u axes respectively. The net of parametric curves (the mesh of latitudes and longitudes on the sphere) corresponds to the net of parallels to the axes in the u,v plane.

The tangent to the curve on the surface corresponding to the curve $u = u(t), v = v(t)$ in the u,v plane has the direction of the vector $\mathbf{x}_t = \frac{d\mathbf{x}}{dt}$, that is,

$$\mathbf{x}_t = (x_t, y_t, z_t) = \left(x_u\frac{du}{dt} + x_v\frac{dv}{dt}, y_u\frac{du}{dt} + y_v\frac{dv}{dt}, z_u\frac{du}{dt} + z_v\frac{dv}{dt}\right) = \mathbf{x}_u\frac{du}{dt} + \mathbf{x}_v\frac{dv}{dt}. \tag{10.64}$$

At a given point on the surface, the tangential vectors $\mathbf{x}_t$ of all curves on the surface passing through that point are linear combinations of two vectors $\mathbf{x}_u, \mathbf{x}_v$ which respectively are tangential to to the parametric lines $v =$ constant and $u =$ constant passing through that point. (e.g., the vectors $\hat{\phi}$ and $\hat{\theta}$ for the spherical polar coordinates on a sphere.) This means that the tangents all lie in the plane through the point *spanned* by the vectors $\mathbf{x}_u$ and $\mathbf{x}_v$, that is, the *tangent plane to the surface* at that point. The *normal* to the surface at that point is perpendicular to all tangential directions, in particular to the vectors $\mathbf{x}_u$ and $\mathbf{x}_v$. Thus, the surface normal is parallel (or antiparallel) to the direction of the vector product

---

[5] This is not always the case. For example, in the representation Eq. (10.59) of the sphere by spherical coordinates, the poles of the sphere correspond to the whole line segments given by $v = 0$ and $v = \pi$.

$$\mathbf{x}_u \times \mathbf{x}_v = (y_u z_v - y_v z_u, z_u x_v - z_v x_u, x_u y_v - x_v y_u). \tag{10.65}$$

One of the most important keys to the understanding of the given surface is the study of the curves that lie on it. Here, we give the expression for the arc length s of such a curve. We start with

$$\left(\frac{ds}{dt}\right)^2 = \left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2 + \left(\frac{dz}{dt}\right)^2 = \mathbf{x}_t \cdot \mathbf{x}_t,$$

so in view of Eq. (10.64) we get

$$\begin{aligned}
\left(\frac{ds}{dt}\right)^2 &= \left(\mathbf{x}_u \frac{du}{dt} + \mathbf{x}_v \frac{dv}{dt}\right) \cdot \left(\mathbf{x}_u \frac{du}{dt} + \mathbf{x}_v \frac{dv}{dt}\right) \\
&= \left(x_u \frac{du}{dt} + x_v \frac{dv}{dt}\right)^2 + \left(y_u \frac{du}{dt} + y_v \frac{dv}{dt}\right)^2 + \left(z_u \frac{du}{dt} + z_v \frac{dv}{dt}\right)^2 \\
&= E\left(\frac{du}{dt}\right)^2 + 2F\left(\frac{du}{dt}\right)\left(\frac{dv}{dt}\right) + G\left(\frac{dv}{dt}\right)^2.
\end{aligned} \tag{10.66}$$

Here, the coefficients E, F, G, the *Gaussian fundamental quantities* of the surface, are given by

$$\begin{aligned}
E &= \left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2 + \left(\frac{\partial z}{\partial u}\right)^2 = \mathbf{x}_u \cdot \mathbf{x}_u \\
F &= \frac{\partial x}{\partial u}\frac{\partial x}{\partial v} + \frac{\partial y}{\partial u}\frac{\partial y}{\partial v} + \frac{\partial z}{\partial u}\frac{\partial z}{\partial v} = \mathbf{x}_u \cdot \mathbf{x}_v \\
G &= \left(\frac{\partial x}{\partial v}\right)^2 + \left(\frac{\partial y}{\partial v}\right)^2 + \left(\frac{\partial z}{\partial v}\right)^2 = \mathbf{x}_v \cdot \mathbf{x}_v
\end{aligned} \tag{10.67}$$

These depend only on $\mathbf{x}_u, \mathbf{x}_v$ and therefore on the surface and its parametric representation and not on the particular choice of the curve on the surface. The expression Eq. (10.66) for the derivative of the length of arc s with respect to the parameter t usually is written symbolically without reference to the parameter used along the curve. One says that the *line element* ds is given by the quadratic differential form ("fundamental form")

$$ds^2 = Edu^2 + 2Fdudv + Gdv^2. \tag{10.68}$$

The length of the cross product $\mathbf{x}_u \times \mathbf{x}_v$ can be expressed in terms of E, F, G as

$$|\mathbf{x}_u \times \mathbf{x}_v|^2 = |\mathbf{x}_u|^2|\mathbf{x}_v|^2 - (\mathbf{x}_u \cdot \mathbf{x}_v)^2 = EG - F^2. \tag{10.69}$$

Our original condition on the parametric representation (inequality Eq. (10.55)) can now be formulated as the condition

$$EG - F^2 > 0 \tag{10.70}$$

for the fundamental quantities.

The direction cosines for one of the two normals to the surface are the components of the unit vector

$$\frac{1}{|\mathbf{x}_u \times \mathbf{x}_v|}\mathbf{x}_u \times \mathbf{x}_v = \frac{1}{\sqrt{EG - F^2}}\mathbf{x}_u \times \mathbf{x}_v.$$

It follows from Eq. (10.65) that the normal to a surface represented parametrically has the direction cosines

$$\cos\alpha = \frac{y_u z_v - y_v z_u}{\sqrt{EG - F^2}},\ \cos\beta = \frac{z_u x_v - z_v x_u}{\sqrt{EG - F^2}},\ \cos\gamma = \frac{x_u y_v - x_v y_u}{\sqrt{EG - F^2}}. \tag{10.71}$$

The tangent to a curve $u = u(t), v = v(t)$ on the surface has the direction of the vector

$$\mathbf{x}_t = \mathbf{x}_u \frac{du}{dt} + \mathbf{x}_v \frac{dv}{dt}.$$

If we now consider a second curve, $u = u(\tau), v = v(\tau)$ on the surface referred to a parameter τ, its tangent has the direction of the vector

$$\mathbf{x}_\tau = \mathbf{x}_u \frac{du}{d\tau} + \mathbf{x}_v \frac{dv}{d\tau}.$$

If the two curves pass through the same point on the surface, the cosine of the angle of intersection ω is the same as the cosine of the angle between $\mathbf{x}_t$ and $\mathbf{x}_\tau$. Hence,

$$\cos\omega = \frac{\mathbf{x}_t \cdot \mathbf{x}_\tau}{|\mathbf{x}_t||\mathbf{x}_\tau|}.$$

We have,

$$\begin{aligned}\mathbf{x}_t\cdot\mathbf{x}_\tau &= \left(\mathbf{x}_u\frac{du}{dt}+\mathbf{x}_v\frac{dv}{dt}\right)\cdot\left(\mathbf{x}_u\frac{du}{d\tau}+\mathbf{x}_v\frac{dv}{d\tau}\right)\\ &= E\frac{du}{dt}\frac{du}{d\tau}+F\left(\frac{du}{dt}\frac{dv}{d\tau}+\frac{du}{d\tau}\frac{dv}{dt}\right)+G\frac{dv}{dt}\frac{dv}{d\tau}. \qquad (10.72)\end{aligned}$$

Consequently, the cosine of the angle between two curves on the surface is given by

$$\cos\omega=\frac{E\frac{du}{dt}\frac{du}{d\tau}+F\left(\frac{du}{dt}\frac{dv}{d\tau}+\frac{du}{d\tau}\frac{dv}{dt}\right)+G\frac{dv}{dt}\frac{dv}{d\tau}}{\sqrt{E\left(\frac{du}{dt}\right)^2+2F\left(\frac{du}{dt}\right)\left(\frac{dv}{dt}\right)+G\left(\frac{dv}{dt}\right)^2}\sqrt{E\left(\frac{du}{d\tau}\right)^2+2F\left(\frac{du}{d\tau}\right)\left(\frac{dv}{d\tau}\right)+G\left(\frac{dv}{d\tau}\right)^2}} \qquad (10.73)$$

We end this subsection by giving one more example of parametrization of a surface which comes up frequently in applications. We consider torus. This is obtained by rotating a circle about a line which lies in the plane of the circle, but does not intersect with it (see Fig. 10.7). We take the axis of rotation as the z-axis and choose the y-axis so as to pass through the center of the circle, whose y-coordinate we denote by a. If the radius of the circle is $r < |a|$, we obtain

$$x=0,\ y-a=r\cos\theta,\ z=r\sin\theta(0\le\theta<2\pi)$$

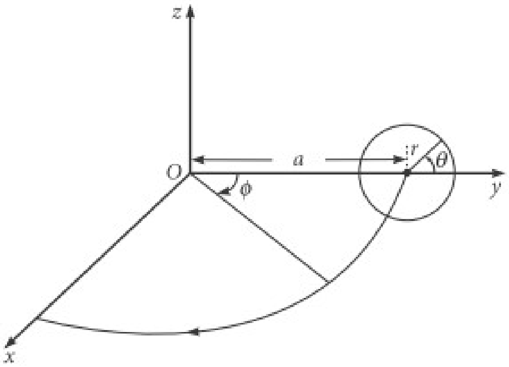

Fig. 10.7 Creation of torus by the rotation of a circle

as a parametric representation of the circle in the $y-z$ plane. Now letting the circle rotate about the z-axis, we find that for each point on the circle x^2+y^2 remains constant; that is, $x^2+y^2=(a+r\cos\theta)^2$. If ϕ is the angle of rotation about the z-axis, we have

$$x \;=\; (a+r\cos\theta)\sin\phi,$$

$$
\begin{aligned}
y &= (a + r\cos\theta)\cos\phi, \\
z &= r\sin\theta
\end{aligned}
\tag{10.74}
$$

with $0 \le \phi < 2\pi, 0 \le \theta < 2\pi$ as a parametric representation of the torus in terms of the parameters θ and ϕ. In this representation the torus appears as the image of the square of side 2π in the θ, ϕ plane. Any pair of boundary points of this square lying on the same line $\theta =$ constant or $\phi =$ constant corresponds to only one point on the surface and the four corners of the square all correspond to the same point on the surface.

Equation (10.67) gives, for the line element on the torus,

$$ds^2 = r^2 d\theta^2 + (a + r\cos\theta)^2 d\phi^2.$$

10.13 The Divergence and the Curl of a Vector Field

We have already seen that the del or the grad operator has vector like structure and it also transforms like a vector under the rotation and translation of the coordinate system. This enables us to formally treat the del operator like a vector with components $\left(\frac{\partial}{\partial x_1}, \frac{\partial}{\partial x_2}, \frac{\partial}{\partial x_3}\right)$ and define its scalar and vector products with vector valued functions possibly giving a vector field.

The divergence

The corresponding scalar product called the divergence of a field is given by

$$\nabla \cdot \mathbf{f}(\mathbf{x}) = \frac{\partial f_1}{\partial x_1} + \frac{\partial f_2}{\partial x_2} + \frac{\partial f_3}{\partial x_3} = \sum_{k=1}^{3} \frac{\partial f_k}{\partial x_k} \tag{10.75}$$

where $f_{1,2,3}(\mathbf{x})$ are the scalar valued component functions of the vector valued function $\mathbf{f}(\mathbf{x})$ with respect to some orthonormal basis (see Eq. (10.1)). If we fix a position vector $\mathbf{x}$, then we get the corresponding vector $\mathbf{f}(\mathbf{x})$ giving us the unique value of the divergence $\nabla \cdot \mathbf{f}(\mathbf{x})$. Thus, the divergence of a vector field is itself a scalar field and we can calculate 'the divergence at a point'. The value of the divergence of a vector field at a point is a measure of how much a vector $\mathbf{f}(\mathbf{x})$ spreads out from (or flows into) the point $\mathbf{x}$ in question. Thus, the vector function in Fig. 10.8(a) has large positive divergence (if the arrows pointed inward it would be a large *negative* divergence), the function in Fig. 10.8(b) has zero divergence and Fig. 10.8(c) again shows a function of positive divergence. Here is a nice possible observation of the divergence phenomenon [9]. Imagine standing at the edge of a pond. Sprinkle some sawdust on the surface. If the material spreads out then you have dropped it at a point of positive divergence; if it collects together, you have dropped it at a point of negative divergence. The vector function $\mathbf{v}$ in this model is the velocity of the water. This is a two dimensional example but it helps give us a feel for the meaning of divergence. A point of positive divergence is a sourse or 'foucet'; a point of negative divergence is a sink or 'drain'.

Exercise In what follows $\mathbf{r}$ denotes a position vector $r = |\mathbf{r}|$ is its magnitude, $\mathbf{A}(\mathbf{r})$ and $\mathbf{B}(\mathbf{r})$ are vector fields, $\phi(\mathbf{r})$ is a scalar field and $f(r)$ is a function of r. All fields and functions have continuous first derivatives. Using Levi-Civita symbols or otherwise, prove the following.

(i) $\nabla \times (\nabla \times \mathbf{A}) = \nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A}$.

(ii) $\mathbf{A} \times (\nabla \times \mathbf{B}) = \nabla_B(\mathbf{A} \cdot \mathbf{B}) - (\mathbf{A} \cdot \nabla)\mathbf{B}$ where ∇_B operates on $\mathbf{B}$ only.

(iii) Given $\nabla \times \mathbf{A} = \mathbf{0} = \nabla \times \mathbf{B}$ show that $\nabla \cdot (\mathbf{A} \times \mathbf{B}) = 0$.

(iv) For constant $\mathbf{a}$ and $\mathbf{b}$ show that $\nabla \times [(\mathbf{a} \times \mathbf{r}) \times \mathbf{b}] = \mathbf{a} \times \mathbf{b}$.

(v) $\nabla \cdot \mathbf{r} = 3$, $\nabla \times \mathbf{r} = \mathbf{0}$, $\nabla(\mathbf{A} \cdot \mathbf{r}) = \mathbf{A}$, $(\mathbf{A} \cdot \nabla)\mathbf{r} = \mathbf{A}$.

(vi) $\nabla r^n = n r^{n-2}\mathbf{r}$, $\nabla \cdot \frac{f(r)\mathbf{r}}{r} = \frac{1}{r^2}\frac{d}{dr}(r^2 f)$.

We will use any one or more of these results in the sequel, as and when required. □

Exercise A particle performs uniform circular motion on a circle of radius r and position vector $\mathbf{r}$. Show that (a) $\nabla \times \mathbf{v} = 2\boldsymbol{\omega}$ and (b) $\nabla \cdot \mathbf{v} = 0$, where $\mathbf{v}$ is the linear velocity and ω is the (constant) rotational velocity of the particle.

Solution

(a) We know that for circular motion, $\mathbf{v} = \boldsymbol{\omega} \times \mathbf{r}$. Therefore,

$$\nabla \times \mathbf{v} = \nabla \times (\boldsymbol{\omega} \times \mathbf{r}) = \boldsymbol{\omega}(\nabla \cdot \mathbf{r}) - \boldsymbol{\omega} \cdot \nabla \mathbf{r}.$$

However, $\nabla \cdot \mathbf{r} = 3$ and $\boldsymbol{\omega} \cdot \nabla \mathbf{r} = \boldsymbol{\omega}$, which gives (a). Thus, we see that the curl operator transforms the velocity vector into a rotational velocity vector.

(b) $\nabla \cdot \mathbf{v} = \nabla \cdot (\boldsymbol{\omega} \times \mathbf{r}) = \mathbf{r} \cdot \nabla \times \boldsymbol{\omega} - \boldsymbol{\omega} \cdot \nabla \times \mathbf{r} = 0$, since $\boldsymbol{\omega}$ is a constant vector and $\nabla \times \mathbf{r} = \mathbf{0}$. □

Thus, there are basically two types of second derivatives, the Laplacian, which is of fundamental importance and the gradient of divergence which we seldom encounter. Since the second derivatives suffice to deal with practically all the physical applications, going over to higher derivatives will reduce to an academic exercise without any physical motivation.

10.14 Differential Operators in Curvilinear Coordinates

A system of curvilinear coordinates, say (u, v, w), is specified via an invertible passive transformation $\mathbb{R}^3 \mapsto \mathbb{R}^3$:

$$(x, y, z) \mapsto (u(x,y,z), v(x,y,z), w(x,y,z)) \tag{10.93}$$

or via the inverse $\mathbb{R}^3 \mapsto \mathbb{R}^3$ transformation

$$(u, v, w) \mapsto (x(u,v,w), y(u,v,w), z(u,v,w)). \tag{10.94}$$

A system of curvilinear coordinates is said to be orthogonal if the coordinate surfaces or equivalently the coordinate lines or the unit vectors tangent to the coordinate lines at their point of intersection are mutually perpendicular (see Fig. 10.11). Note that there are different sets of coordinate surfaces, coordinate lines and the orthogonal basis vectors $\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}}$ at different points in space. The transformations in Eqs (10.93), (10.94) are assumed to be C^1, that is, having continuous partial derivatives at all points in some region of space, as well as invertible everywhere in that region, that is, having a non-zero Jacobian determinant at all points in that region. Such transformations between two sets of coordinates are called *admissible* coordinate transformations defined over a given region of space. Just to refresh our memory, we recall the definitions of the coordinate lines and coordinate surfaces. Given any point, one can draw a curve passing through the point in such a way that only one of the three curvilinear coordinates changes along the curve while the values of the other two coordinates remain constant. For three curvilinear coordinates one can draw three such curves, all passing through the given point and mutually intersecting at right angles. Each is called a *coordinate curve* or a *coordinate line* and a surface passing through the given point on which a particular curvilinear coordinate has a constant value is called a *coordinate surface.* The u-coordinate line, for example, is the curve of intersection of the v and the w coordinate surfaces. All this is depicted in Fig. 10.11.

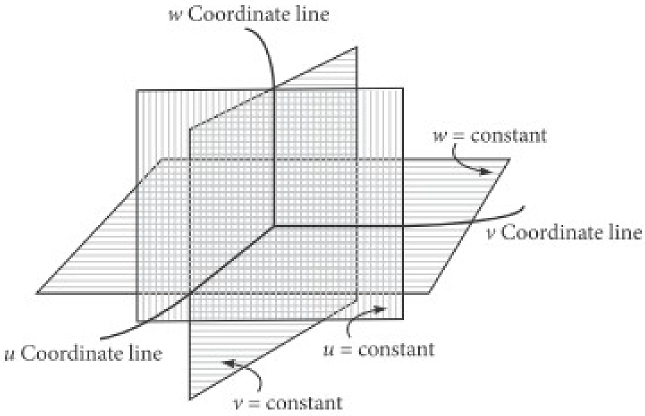

Fig. 10.11 The Network of coordinate lines and coordinate surfaces at any arbitary point, defining a curvilinear coordinate system

Let the equations for the coordinate curves at a point (u_0, v_0, w_0) be

$$\mathbf{x} = \mathbf{x}(u, v_0, w_0) \;\; \mathbf{x} = \mathbf{x}(u_0, v, w_0) \;\; \mathbf{x} = \mathbf{x}(u_0, v_0, w).$$

The tangents to the coordinate curves are given by the vectors

$$\frac{\partial \mathbf{x}(u, v_0, w_0)}{\partial u}, \frac{\partial \mathbf{x}(u_0, v, w_0)}{\partial v}, \frac{\partial \mathbf{x}(u_0, v_0, w)}{\partial w}$$

respectively. Orthogonality of these vectors requires that

$$\frac{\partial \mathbf{x}}{\partial u} \cdot \frac{\partial \mathbf{x}}{\partial v} = \frac{\partial \mathbf{x}}{\partial u} \cdot \frac{\partial \mathbf{x}}{\partial w} = \frac{\partial \mathbf{x}}{\partial v} \cdot \frac{\partial \mathbf{x}}{\partial w} = 0.$$

We are interested in the differential displacement $d\mathbf{x}$ as we go from $\mathbf{x}(u,v,w)$ to $\mathbf{x}(u+du, v+dv, w+dw)$. We have, in terms of the corresponding Jacobian matrix,

$$d\mathbf{x} = \begin{bmatrix} \frac{\partial s_1}{\partial u} & \frac{\partial s_1}{\partial v} & \frac{\partial s_1}{\partial w} \\ \frac{\partial s_2}{\partial u} & \frac{\partial s_2}{\partial v} & \frac{\partial s_2}{\partial w} \\ \frac{\partial s_3}{\partial u} & \frac{\partial s_3}{\partial v} & \frac{\partial s_3}{\partial w} \end{bmatrix} \begin{bmatrix} du \\ dv \\ dw \end{bmatrix} = \frac{\partial \mathbf{x}}{\partial u} du + \frac{\partial \mathbf{x}}{\partial u} dv + \frac{\partial \mathbf{x}}{\partial w} dw = \mathbf{x}_u du + \mathbf{x}_v dv + \mathbf{x}_w dw. \tag{10.95}$$

where $s_{1,2,3}(u,v,w) = \mathbf{x}(u,v,w) \cdot \{\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}}\}$ are the components of $\mathbf{x}$ in the $\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}}$ mutually orthogonal directions. This defines the line element $ds = |d\mathbf{x}|$ via

$$\begin{aligned} ds^2 = d\mathbf{x} \cdot d\mathbf{x} &= \mathbf{x}_u \cdot \mathbf{x}_u du^2 + \mathbf{x}_v \cdot \mathbf{x}_v dv^2 + \mathbf{x}_w \cdot \mathbf{x}_w dw^2 \\ &= h_1^2 du^2 + h_2^2 dv^2 + h_3^2 dw^2. \end{aligned} \tag{10.96}$$

The parameters h_1, h_2, h_3 are the analogues of the Gaussian fundamental quantities E, F, G of a surface, we derived before. They relate the differential displacements along the $\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}}$ directions as a result of the displacement $d\mathbf{x}$ to the diferentials du, dv, dw via

$$d\mathbf{x} = ds_1 \hat{\mathbf{u}} + ds_2 \hat{\mathbf{v}} + ds_3 \hat{\mathbf{w}} = h_1 du \hat{\mathbf{u}} + h_2 dv \hat{\mathbf{v}} + h_3 dw \hat{\mathbf{w}}.$$

Thus, the volume of the rectangular parallelepiped with sides ds_1, ds_2, ds_3 is given by

$$dV = ds_1 ds_2 ds_3 = h_1 h_2 h_3 du dv dw.$$

The product $h_1 h_2 h_3$ ensures that the the last term has the dimension of volume; as the curvilinear coordinates can be dimensionless quantities like angles.

The u coordinate surface passing through the point (u_0, v_0, w_0) is the collection of points (x, y, z) satisfying $u(x, y, z) = u_0$ and similarly, the v and w coordinate surfaces are given by $v(x, y, z) = v_0$ and $w(x, y, z) = w_0$, where (x, y, z) are the Cartesian coordinates with respect to some rectangular Cartesian coordinate system. We can vary the point (u_0, v_0, w_0) over the region for which the curvilinear coordinate transformations, Eqs (10.93), (10.94), are defined. Therefore, we can replace u_0, v_0, w_0 in the equations defining the coordinate surfaces by u, v, w and say that a particular triad of coordinate surfaces emerges when particular values of u, v and w are substituted on the RHS of these equations. Thus, we write, for the equations defining the coordinate surfaces

$$u = u(x, y, z) \quad v = v(x, y, z) \quad w = w(x, y, z).$$

The normals to the coordinate surfaces are given by $\nabla u, \nabla v, \nabla w$ (see section 10.8) which, owing to orthogonality, must satisfy

$$0 = \nabla u \cdot \nabla v = \nabla u \cdot \nabla w = \nabla v \cdot \nabla w.$$

The vectors normal to the coordinate surfaces are tangent to the corresponding coordinate curves so that we can *define* the fundamental triad for the curvilinear coordinates as

$$\hat{\mathbf{u}} = \frac{\nabla u}{|\nabla u|} \quad \hat{\mathbf{v}} = \frac{\nabla v}{|\nabla v|} \quad \hat{\mathbf{w}} = \frac{\nabla w}{|\nabla w|}. \tag{10.97}$$

Let $d\mathbf{s}_1 = ds_1\hat{\mathbf{u}}$, $d\mathbf{s}_2 = ds_2\hat{\mathbf{v}}$, $d\mathbf{s}_3 = ds_3\hat{\mathbf{w}}$ be the differential displacement along the $\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}}$ directions. Since $\nabla u, \nabla v, \nabla w$ have the same values in all the orthonormal basis triads and since $\nabla u, d\mathbf{s}_1$, $\nabla v, d\mathbf{s}_2$ and $\nabla w, d\mathbf{s}_3$ are the pairs of parallel vectors, we can write,

$$\begin{aligned} du &= \nabla u \cdot d\mathbf{s}_1 = |\nabla u||d\mathbf{s}_1|, \\ dv &= \nabla v \cdot d\mathbf{s}_2 = |\nabla v||d\mathbf{s}_2|, \\ dw &= \nabla w \cdot d\mathbf{s}_3 = |\nabla w||d\mathbf{s}_3|. \end{aligned} \tag{10.98}$$

This gives,

$$ds^2 = ds_1^2 + ds_2^2 + ds_3^2 = \frac{du^2}{|\nabla u|^2} + \frac{dv^2}{|\nabla v|^2} + \frac{dw^2}{|\nabla w|^2}. \tag{10.99}$$

Comparing equations Eqs (10.96) and (10.99) we get

$$\begin{aligned} h_1 &= \frac{1}{|\nabla u|} = \sqrt{\mathbf{x}_u \cdot \mathbf{x}_u} \text{ impling } \hat{\mathbf{u}} = \mathrm{h}_1 \nabla \mathrm{u}, \\ h_2 &= \frac{1}{|\nabla v|} = \sqrt{\mathbf{x}_v \cdot \mathbf{x}_v} \text{ impling } \hat{\mathbf{v}} = \mathrm{h}_2 \nabla \mathrm{v}, \\ h_3 &= \frac{1}{|\nabla w|} = \sqrt{\mathbf{x}_w \cdot \mathbf{x}_w} \text{ impling } \hat{\mathbf{w}} = \mathrm{h}_3 \nabla \mathrm{w}. \end{aligned} \tag{10.100}$$

Example For spherical polar coordinates we identify $u = r$, $v = \theta$ and $w = \phi$, where

$$r = \sqrt{x^2 + y^2 + z^2},\ \theta = \cos^{-1}\left(\frac{z}{\sqrt{x^2 + y^2 + z^2}}\right) \text{ and } \phi = \tan^{-1}\left(\frac{\mathrm{y}}{\mathrm{x}}\right).$$

This gives $h_1^{-1} = |\nabla r| = 1$, $h_2^{-1} = |\nabla \theta| = r^{-1}$ and $\mathrm{h}_3^{-1} = |\nabla \phi| = (\mathrm{r}\sin\theta)^{-1}$. Therefore,

$$ds^2 = h_1^2 dr^2 + h_2^2 d\theta^2 + h_3^2 d\phi^2 = dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\phi^2.$$

Also, the fundamental triad is,

$$\hat{\mathbf{u}} = \hat{\mathbf{r}}, \ \ \hat{\mathbf{v}} = \hat{\theta}, \ \ \hat{\mathbf{w}} = \hat{\phi}.$$

We can also invert the transformation to get

$$x = r\sin\theta\cos\phi \ \ y = r\sin\theta\sin\phi \ \ z = r\cos\theta.$$

This gives (Exercise),

$$\begin{aligned} h_1 &= \sqrt{\left(\frac{dx}{dr}\right)^2 + \left(\frac{dy}{dr}\right)^2 + \left(\frac{dz}{dr}\right)^2} = 1, \\ h_2 &= \sqrt{\left(\frac{dx}{d\theta}\right)^2 + \left(\frac{dy}{d\theta}\right)^2 + \left(\frac{dz}{d\theta}\right)^2} = r, \\ h_3 &= \sqrt{\left(\frac{dx}{d\phi}\right)^2 + \left(\frac{dy}{d\phi}\right)^2 + \left(\frac{dz}{d\phi}\right)^2} = r\sin\theta. \end{aligned} \tag{10.101}$$

which are identical to those already obtained from forward transformations.

The gradient of a scalar valued function $\phi(u,v,w)$ with respect to the Cartesian coordinates x,y,z can be obtained by applying chain rule:

$$\begin{aligned} \nabla\phi &= \frac{\partial\phi}{\partial u}\nabla u + \frac{\partial\phi}{\partial v}\nabla v + \frac{\partial\phi}{\partial w}\nabla w \\ &= \left(\frac{1}{h_1}\frac{\partial\phi}{\partial u}\right)\hat{\mathbf{u}} + \left(\frac{1}{h_2}\frac{\partial\phi}{\partial v}\right)\hat{\mathbf{v}} + \left(\frac{1}{h_3}\frac{\partial\phi}{\partial w}\right)\hat{\mathbf{w}}, \end{aligned} \tag{10.102}$$

where we have used Eq. (10.100).

Our next job is to express the divergence $\nabla \cdot \mathbf{f}$ of a vector field $\mathbf{f}$ exclusively in terms of the derivatives with respect to the curvilinear coordinates u,v,w. We can do this, in principle, by a systematic application of the chain rule, but that will make us go through a lengthy algebra which only masochists can enjoy. There is a short cut, where we use the fact that the flux of a vector field through a differential volume dV is given by $\nabla \cdot \mathbf{f} dV$. In order to get hold of this quantity, we need to know how to represent the area of a piece of a surface by a vector. As shown in Fig. 10.12, an element of area da is represented by the vector $d\mathbf{a}$ given by

$$d\mathbf{a} = \hat{\mathbf{n}} da = da_x \hat{\mathbf{i}} + da_y \hat{\mathbf{j}} + da_z \hat{\mathbf{k}} \tag{10.103}$$

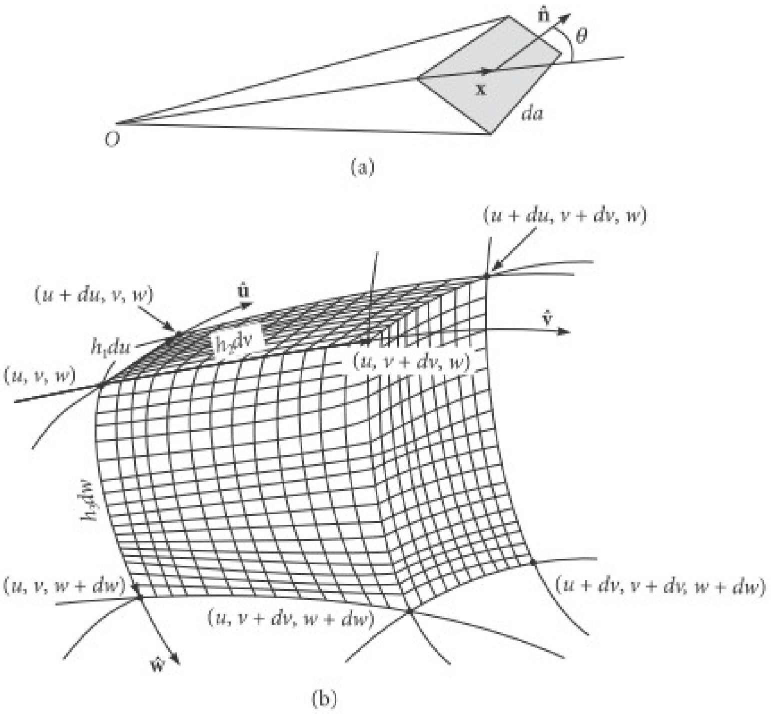
where $\hat{\mathbf{n}}$ is the unit outward normal to the surface, defined via its direction cosines

$$\hat{\mathbf{n}} = \cos\alpha\hat{\mathbf{i}} + \cos\beta\hat{\mathbf{j}} + \cos\gamma\hat{\mathbf{k}}. \tag{10.104}$$

Therefore, the components of $d\mathbf{a}$ are given by

$$da_x = da\cos\alpha, \;\; da_y = da\cos\beta \;\; da_z = da\cos\gamma.$$

In particular, $\mathbf{x}\cdot d\mathbf{a} = |\mathbf{x}|da\cos\theta$ where θ is the angle between $\hat{\mathbf{n}}$ and $\mathbf{x}$. If $\theta = 0$ or $\theta = \pi$ then $\mathbf{x}\cdot d\mathbf{a} = \pm|\mathbf{x}|da$. This situation arises when the surface is perpendicular to $\mathbf{x}$, that is, the area of the projection of the surface element on the plane perpendicular to $\mathbf{x}$ is the same as da. The flux of $\mathbf{f}$ through an element of area $d\mathbf{a}$ is $\mathbf{f}\cdot d\mathbf{a}$.



(a)

(b)

Fig. 10.12 (a) Evaluating $\mathbf{x}\cdot d\mathbf{a}$ (b) Flux through the opposite faces of a volume element

Let us now consider a differential volume of the shape of a rectangular parallelepiped with sides ds_1, ds_2, ds_3 defined above so that its volume is $dV = ds_1 ds_2 ds_3 = h_1 h_2 h_3 \, du dv dw$. Let us assume that the pairs $-\hat{\mathbf{u}}, \hat{\mathbf{u}}$ be the outward normals to the front and the back sides, $-\hat{\mathbf{v}}, \hat{\mathbf{v}}$ be the outward normals to the left and the right sides and $-\hat{\mathbf{w}}, \hat{\mathbf{w}}$ be the outward normals to the bottom and the top sides of the box. Then for the front face, $d\mathbf{a} = -h_2 h_3 dv dw \hat{\mathbf{u}}$ and $\mathbf{f}\cdot d\mathbf{a} = -(h_2 h_3 f_1) dv dw$, where $f_{1,2,3}$ are the components of $\mathbf{f}$

along $\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}}$ respectively and the product $h_2 h_3 f_1$ is to be evaluated at u. On the back face, product $h_2 h_3 f_1$ is to be evaluated at $u + du$ so that $\mathbf{f} \cdot d\mathbf{a} = (h_2 h_3 f_1 + \frac{\partial}{\partial u}(h_2 h_3 f_1) du) dv dw$. Therefore, the net flux through the front and back pair of faces is

$$\left[\frac{\partial}{\partial u}(h_2 h_3 f_1)\right] du dv dw = \frac{1}{h_1 h_2 h_3} \frac{\partial}{\partial u}(h_2 h_3 f_1) dV.$$

In the same way, the right and the left sides give

$$\frac{1}{h_1 h_2 h_3} \frac{\partial}{\partial v}(h_1 h_3 f_2) dV$$

and the bottom and the top sides contribute

$$\frac{1}{h_1 h_2 h_3} \frac{\partial}{\partial w}(h_1 h_2 f_3) dV.$$

Thus, the total flux through the box is given by

$$(\nabla \cdot \mathbf{f}) dV = \frac{1}{h_1 h_2 h_3}\left[\frac{\partial}{\partial u}(h_2 h_3 f_1) + \frac{\partial}{\partial v}(h_1 h_3 f_2) + \frac{\partial}{\partial w}(h_1 h_2 f_3)\right] dV$$

This gives

$$\nabla \cdot \mathbf{f} = \frac{1}{h_1 h_2 h_3}\left[\frac{\partial}{\partial u}(h_2 h_3 f_1) + \frac{\partial}{\partial v}(h_3 h_1 f_2) + \frac{\partial}{\partial w}(h_1 h_2 f_3)\right]. \tag{10.105}$$

Combining Eq. (10.105) with Eq. (10.102) we get, for the Laplacian operator,

$$\nabla^2 \phi = \nabla \cdot \nabla \phi = \frac{1}{h_1 h_2 h_3}\left[\frac{\partial}{\partial u}\left(\frac{h_2 h_3}{h_1}\frac{\partial \phi}{\partial u}\right) + \frac{\partial}{\partial v}\left(\frac{h_3 h_1}{h_2}\frac{\partial \phi}{\partial v}\right) + \frac{\partial}{\partial w}\left(\frac{h_1 h_2}{h_3}\frac{\partial \phi}{\partial w}\right)\right]. \tag{10.106}$$

Our last task in this subsection is to express the curl $\nabla \times \mathbf{f}$ of a vector field $\mathbf{f}$ in terms of the derivatives with respect to the curvilinear coordinates u, v, w. The principle we follow for this is

Circulation of $\mathbf{f}$ around a loop enclosing an infinitesimal area $d\mathbf{a} = (\nabla \times \mathbf{f}) \cdot d\mathbf{a}$.

The sense of circulation is given by that which makes a right handed screw advance in the direction of $d\mathbf{a}$. The required circulation can be explicitly calculated for an infinitesimal loop of rectangular shape. For each side of the rectangle, we have to find the scalar product of $\mathbf{f}$ with the vector along the side and in the direction consistent with the sense of circulation. In the first place, the surface enclosed by an infinitesimal loop can be taken to be a plane. Consider such a rectangular loop in the $\hat{\mathbf{u}}, \hat{\mathbf{v}}$ plane, with $\hat{\mathbf{w}}$ normal to it (see Fig. 10.13). From Fig. 10.13 and $\hat{\mathbf{w}}$ pointing out of the page, it is clear that the sense of circulation which makes a right handed screw advance in $\hat{\mathbf{w}}$ direction is counterclockwise, as shown. The vector on the side along $\hat{\mathbf{u}}$ is $d\mathbf{s}_1 = h_1 du\hat{\mathbf{u}}$ that on the side along $\hat{\mathbf{v}}$ is $d\mathbf{s}_2 = h_2 dv\hat{\mathbf{v}}$ and area

$$d\mathbf{a} = h_1 h_2 du dv \hat{\mathbf{w}}.$$

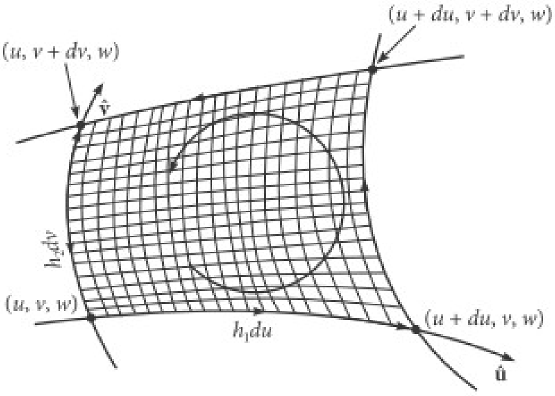


Fig. 10.13 Circulation around a loop

Along the bottom side (along $\hat{\mathbf{u}}$) the contribution of $\mathbf{f}$ to circulation is

$$\mathbf{f} \cdot d\mathbf{s}_1 = h_1 f_1 du$$

Along the top side, the sign is reversed and $h_1 f_1$ is evaluated at $v + dv$ rather than v. Both sides together give

$$\left[-(h_1 f_1)\Big|_{v+dv} + (h_1 f_1)\Big|_{v} \right] du = -\left[\frac{\partial}{\partial v}(h_1 f_1) \right] du dv.$$

Similarly, the right and the left sides yield

$$\left[\frac{\partial}{\partial u}(h_2 f_2) \right] du dv.$$

So, the total circulation is

$$\left[\frac{\partial}{\partial u}(h_2 f_2) - \frac{\partial}{\partial v}(h_1 f_1) \right] du dv = \frac{1}{h_1 h_2} \left[\frac{\partial}{\partial u}(h_2 f_2) - \frac{\partial}{\partial v}(h_1 f_1) \right] \hat{\mathbf{w}} \cdot d\mathbf{a}.$$

The coefficient of $d\mathbf{a}$ serves to define the w component of the curl. Constructing the u and v components in the same way, we get

$$\begin{aligned}\nabla\times\mathbf{f} \;=\; & \frac{1}{h_2h_3}\left[\frac{\partial}{\partial v}(h_3f_3)-\frac{\partial}{\partial w}(h_2f_2)\right]\hat{\mathbf{u}}+\frac{1}{h_1h_3}\left[\frac{\partial}{\partial w}(h_1f_1)-\frac{\partial}{\partial u}(h_3f_3)\right]\hat{\mathbf{v}}\\ & +\;\frac{1}{h_1h_2}\left[\frac{\partial}{\partial u}(h_2f_2)-\frac{\partial}{\partial v}(h_1f_1)\right]\hat{\mathbf{w}}.\end{aligned}\tag{10.107}$$

This expression for $\nabla\times\mathbf{f}$ can be written in a compact determinantal form as

$$\nabla\times\mathbf{f}=\frac{1}{h_1h_2h_3}\begin{vmatrix} h_1\hat{\mathbf{u}} & h_2\hat{\mathbf{v}} & h_3\hat{\mathbf{w}}\\ \frac{\partial}{\partial u} & \frac{\partial}{\partial v} & \frac{\partial}{\partial w}\\ h_1f_1 & h_2f_2 & h_3f_3\end{vmatrix}.\tag{10.108}$$

Exercise Express the vector derivatives, that is, gradient, divergence, curl and Laplacian in terms of (a) spherical polar and (b) cylindrical coordinates for a scalar field $u(\mathbf{x})$ and a vector field $\mathbf{v}(\mathbf{x})$.

Answer

(a) Gradient:

$$\nabla u=\frac{\partial u}{\partial r}\hat{\mathbf{r}}+\frac{1}{r}\frac{\partial u}{\partial\theta}\hat{\theta}+\frac{1}{r\sin\theta}\frac{\partial u}{\partial\phi}\hat{\phi}.$$

Divergence:

$$\nabla\cdot\mathbf{v}=\frac{1}{r^2}\frac{\partial}{\partial r}(r^2v_r)+\frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}(\sin\theta v_\theta)+\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial\phi}.$$

Curl:

$$\begin{aligned}\nabla\times\mathbf{v}=&\frac{1}{r\sin\theta}\left[\frac{\partial}{\partial\theta}(\sin\theta v_\phi)-\frac{\partial v_\theta}{\partial\phi}\right]\hat{\mathbf{r}}+\frac{1}{r}\left[\frac{1}{\sin\theta}\frac{\partial v_r}{\partial\phi}-\frac{\partial}{\partial r}(rv_\phi)\right]\\ &\hat{\theta}+\frac{1}{r}\left[\frac{\partial}{\partial r}(rv_\theta)-\frac{\partial v_r}{\partial\theta}\right]\hat{\phi}.\end{aligned}$$

Laplacian:

$$\nabla^2u=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial u}{\partial r}\right)+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial u}{\partial\theta}\right)+\frac{1}{r^2\sin^2\theta}\frac{\partial^2u}{\partial\phi^2}.$$

(b) Gradient:

$$\nabla u=\frac{\partial u}{\partial\rho}\hat{\rho}+\frac{1}{\rho}\frac{\partial u}{\partial\phi}\hat{\phi}+\frac{\partial u}{\partial z}\hat{\mathbf{z}}.$$

Divergence:

$$\nabla \cdot \mathbf{v} = \frac{1}{\rho}\frac{\partial}{\partial \rho}(\rho v_\rho) + \frac{1}{\rho}\frac{\partial v_\phi}{\partial \phi} + \frac{\partial v_z}{\partial z}.$$

Curl:

$$\nabla \times \mathbf{v} = \left(\frac{1}{\rho}\frac{\partial v_z}{\partial \phi} - \frac{\partial v_\phi}{\partial z}\right)\hat{\rho} + \left(\frac{\partial v_\rho}{\partial z} - \frac{\partial v_z}{\partial \rho}\right)\hat{\phi} + \frac{1}{\rho}\left(\frac{\partial}{\partial \rho}(\rho v_\phi) - \frac{\partial v_\rho}{\partial \phi}\right)\hat{\mathbf{z}}.$$

Laplacian:

$$\nabla^2 u = \frac{1}{\rho}\frac{\partial}{\partial \rho}\left(\rho \frac{\partial u}{\partial \rho}\right) + \frac{1}{\rho^2}\frac{\partial^2 u}{\partial \phi^2} + \frac{\partial^2 u}{\partial z^2}.$$

Chapter 13

Straight Line

13.1 INTRODUCTION

The intersection of two planes P_1 and P_2 is the locus of all the common points on both the planes P_1 and P_2. This locus is a straight line. Any given line can be uniquely determined by any of the two planes containing the line. Thus, a line can be regarded as the locus of the common points of two intersecting planes.

Let us consider the two planes

$$ax + by + cz + d = 0 \qquad (13.1)$$

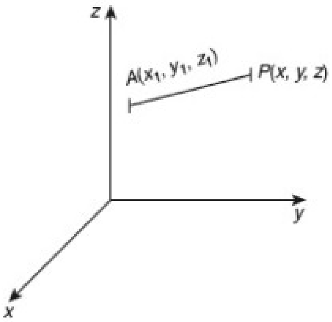
$$a_1x + b_1y + c_1z + d_1 = 0 \qquad (13.2)$$

Any set of coordinates (*x*, *y*, *z*) which satisfy these two equations simultaneously will represent a point on the line of intersection of these two planes. Hence these two equations taken together will represent a straight line. It can be noted that the equation of *x*–axis are $y = 0$, $z = 0$. The equation of the *y*–axis is $x = 0$, $z = 0$ and the equation of the *z*–axis is $x = 0$, $y = 0$. The representation of the straight line by the equations $ax + by + cz + d = 0$ and $a_1x + b_1y + c_1z + d_1 = 0$ is called non–symmetrical form. Let us now derive the equations of a straight line in the symmetrical form.

13.2 EQUATION OF A STRAIGHT LINE IN SYMMETRICAL FORM

Let $A(x_1, y_1, z_1)$ be a point on the straight line and $P(x, y, z)$ be any point on the straight line. Let *l*, *m*, *n* be the direction cosines of the straight line. Let $OP = r$. The projections of *AP* on the coordinate axes are $x - x_1$, $y - y_1$, $z - z_1$. Also the projections of *AP* on the coordinate axes are given by *lr*, *mr*, *nr*. Then $x - x_1 = lr$, $y - y_1 = mr$ and $z - z_1 = nr$.

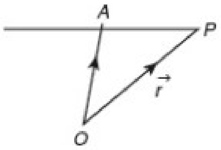
$$\therefore \frac{x-x_1}{l} = \frac{y-y_1}{m} = \frac{z-z_1}{n} = r$$



These equations are called the symmetrical form of the straight line.

Aliter:

We now derive the equations in symmetrical form from the vector equation of the straight line passing through a point and parallel to a vector.



Let A be a given point on a straight line and P be any point on the straight line. Let $\vec{b}$ be a vector parallel to the line. Let O be the origin and $\overline{OA} = \vec{a}, \overline{OP} = \vec{r}$.

Then

$$\overrightarrow{AP} = \overrightarrow{OP} - \overrightarrow{OA} = \vec{r} - \vec{a} \qquad (13.3)$$

But

$$\overrightarrow{AP} = t\vec{b} \qquad (13.4)$$

where t is a scalar.

From (13.3) and (13.4),

$$\vec{r} - \vec{a} = t\vec{b} \text{ or } \vec{r} = \vec{a} + t\vec{b} \qquad (13.5)$$

This equation is true for all positions of P on the straight line and therefore this is the vector equation of the straight line. Let

$\overline{OP} = x\vec{i} + y\vec{j} + z\vec{k}, \overline{OA} = x_1\vec{i} + y_1\vec{j} + z_1\vec{k}$ and $\vec{b} = l\vec{i} + m\vec{j} + n\vec{k}$.

Then from equation (13.4), we have

$$(x - x_1)\vec{i} + (y - y_1)\vec{j} + (z - z_1)\vec{k} = t\vec{b} = t(l\vec{i} + m\vec{j} + n\vec{k})$$

Equating the coefficients of $\vec{i}$, $\vec{j}$ and $\vec{k}$, we have

$$x - x_1 = tl, \quad y - y_1 = tm, \quad z - z_1 = tn$$

$$\therefore \frac{x - x_1}{l} = \frac{y - y_1}{m} = \frac{z - z_1}{n} = t$$

These are the cartesian equations of the straight line in symmetrical form.

Note 13.2.1: To express the equations of a straight line in symmetrical form we require (i) the coordinate of a point on the line and (ii) the direction cosines of the straight line.

Note 13.2.2: Any point on this line is $(x_1 + lr, y_1 + mr, z_1 + nr)$. Even if l, m and n are the direction ratios of the line, $(x_1 + lr, y_1 + mr, z_1 + nr)$ will represent a point on the line but r will not be distance between the points (x, y, z) and (x_1, y_1, z_1).

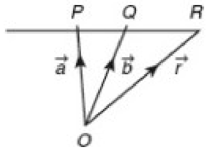
13.3 EQUATIONS OF A STRAIGHT LINE PASSING THROUGH THE TWO GIVEN POINTS

Let $P(x_1, y_1, z_1)$ and $Q(x_2, y_2, z_2)$ be two given points. The direction ratios of the line are $x_2 - x_1, y_2 - y_1, z_2 - z_1$.

Therefore, the equations of the straight line are $\frac{x - x_1}{x_2 - x_1} = \frac{y - y_1}{y_2 - y_1} = \frac{z - z_1}{z_2 - z_1}$.

Aliter:

Let *O* be the origin and *P* and *Q* be the points on the straight line and *R* be any point on the straight line.



$$\overline{OP} = \vec{a}, \overline{OQ} = \vec{b}, \overline{OR} = \vec{r}$$

Then $\overline{PQ} = \overline{OQ} - \overline{OP} = \vec{b} - \vec{a}$. Also $\overline{PR} = \overline{OR} - \overline{OP} = \vec{r} - \vec{a}$.

But $\overline{PR} = t\overline{PQ}$ (i.e.) $\vec{r} - \vec{a} = t(\vec{b} - \vec{a})$

$$\vec{r} = \vec{a} + t(\vec{b} - \vec{a}) \qquad (13.6)$$

This is the vector equation of the straight line.

Let $\vec{r} = x\vec{i} + y\vec{j} + z\vec{k}, \vec{a} = x_1\vec{i} + y_1\vec{i} + z_1\vec{k}, \vec{b} = x_2\vec{i} + y_2\vec{j} + z_2\vec{k}$.

Then from (13.6), we get

$(x - x_1)\vec{i} + (y - y_1)\vec{j} + (z - z_1)\vec{k} = t[(x_2 - x_1)\vec{i} +$

Equating the coefficients of $\vec{i}$, $\vec{j}$ and $\vec{k}$, we get

$$x - x_1 = t(x_2 - x_1); y - y_1 = t(y_2 - y_1); z - z_1 = k(z_2 - z_1)$$

$$\therefore \frac{x - x_1}{x_2 - x_1} = \frac{y - y_1}{y_2 - y_1} = \frac{z - z_1}{z_2 - z_1} = t$$

quantum chromodynamics, and continues to inspire the searches for grand unified theories and the alluring prospects of string theory. Cartan's torsion remains important in the search for quantum gravity, as does Riemannian geometry itself.

All this takes us back to Riemann, whom we should not merely admire as a forerunner but whose vision still holds future prospects. His 1854 remarks about the possibilities that the spatial fabric might break down into discrete "quanta" at very small distances have become the focus of much speculation in the quest for a complete theory of quantum gravity. Many physicists now envisage that some radical change in the nature of space-time occurs near the Planck length, $\sqrt{\frac{hG}{2\pi c^3}} = 1.6 \times 10^{-35}$ m, at which point they anticipate something like a discrete manifold, no longer continuous, as Riemann had suggested. Non-relativistic quantum theory implies that we cannot build clocks and measuring rods not just at atomic scales (the smallest fully functional clock is about the size of a small microorganism); relativistic quantum theory draws from the invariance of the speed of light yet more stringent limitations on the possible measurement of physical quantities.[47] Unlike the problem of rigid bodies, which could be circumvented by light rays and falling particles, these quantum limitations seem more fundamental, ultimately connected with the radical indistinguishability of quanta and the infinite-dimensional Hilbert space mandated by quantum theory.[48]

At whatever scale the issue is joined, though, physicists largely subscribe to Riemann's insight that "upon the exactness with which we pursue phenomena into the infinitely small, does our knowledge of their causal connections essentially depend." He, like Gauss and Lobachevsky before him, also directed our attention to astronomical consequences of the varying curvature of space. Most of all, we realize more and more clearly the force of his insight that "either the reality underlying space must form a discrete manifold, or the basis for the metric relations must be sought outside it, in binding forces acting upon it." Both general relativity and the still-undiscovered theories that will correct and transcend it must struggle, in their own ways, with the quest for these "binding forces," though quantum theory remains the touchstone whose existence Riemann did not suspect and Einstein too much resisted.

This leaves us at the threshold of myriad possibilities that challenge us to add, in our turn, our own ideas of what we think lies "at the foundations of geometry." If space-time is not truly ultimate, what other mathematical structures might lie beneath? Loop quantum gravity aspires to build up space-time without presupposing it. String theory incorporates general relativity into a larger theoretical structure, but does it implicitly rest on accepting space-time as a given backdrop or can it lead to other possibilities?[49] Yet we still lack a fundamental understanding even of the entire range of possibilities. Let me pose the larger question: what are all the possible mathematical structures that could give rise to the *appearance* of space-time, as we know it? This mathematical challenge then leads us to reflect on how, physically, we should judge between the possible alternatives. Once we have left behind the remnants of the

For this purpose, one constructs the system of shortest lines emanating from a given point; the position of an arbitrary point can then be determined by the initial direction of the shortest line in which it lies, and its distance, in this line, from the initial point.[12] It can therefore be expressed by the ratios of the quantities dx^0, i.e., the quantities dx at the origin of this shortest line, and by the length s of this line. In place of the dx^0 one now introduces linear expressions $d\alpha$ formed from them in such a way that the initial value of the square of the line element will be equal to the sum of the squares of these expressions, so that the independent variables are: the quantity s and the ratio of the quantities $d\alpha$. Finally, in place of the $d\alpha$ choose quantities x_1, x_2,..., x_n proportional to them, but such that the sum of their squares equals s^2. If one introduces these quantities, then for infinitely small values of x the square of the line element $= \sum dx^2$, but the next order term in its expansion equals a homogeneous expression of the second degree in the $n\frac{n-1}{2}$ quantities $(x_1dx_2 - x_2dx_1)$, $(x_1dx_3 - x_3dx_1)$,..., and is consequently an infinitely small quantity of the fourth order, so that one obtains a finite quantity if one divides it by the square of the infinitely small triangle at whose vertices the variables have the values $(0, 0, 0, ...)$, $(x_1, x_2, x_3, ...)$, $(dx_1, dx_2, dx_3, ...)$. This quantity remains the same as long as the quantities x and dx are contained in the same binary linear forms, or as long as the two shortest lines from the initial point to x and from the initial point to dx remain in the same surface element, and therefore depends only on the position and direction of that element. It obviously $=$ zero if the manifold in question is flat, i.e., if the square of the line element is reducible to $\sum dx^2$, and can therefore be regarded as the measure of deviation from flatness in this surface direction at this point. When multiplied by $-\frac{3}{4}$ it becomes equal to the quantity which Privy Councilor Gauss has called the curvature of a surface.[13] Previously, $n\frac{n-1}{2}$ functions of position were found necessary in order to determine the metric relations of an n-fold extended manifold representable in the assumed form; hence if the curvature is given in $n\frac{n-1}{2}$ surface directions at every point, then the metric relations of the manifold may be determined, provided only that no identical relations can be found between these values, and indeed in general this does not occur. The metric relations of these manifolds, in which the line element can be represented as the square root of a differential expression of the second degree, can thus be expressed in a way completely independent of the choice of the varying quantities. A similar path to the same goal could also be taken in those manifolds in which the line element is expressed in a less simple way, e.g., by the fourth root of a differential expression of the fourth degree. The line element in this more general case would not be reducible to the square root of a quadratic sum of differential expressions, and therefore in the expression for the square of the line element the deviation from flatness would be an infinitely small quantity of the second order, whereas for the other manifolds it was an infinitely small quantity of the fourth order. This peculiarity of the latter manifolds therefore might well be called flatness in the smallest parts. For present purposes, however, the most important peculiarity of these manifolds, on whose

Remark. The normal curvature of C does not depend on the orientation of C but changes sign with a change of orientation for the surface.

To give an interpretation of the second fundamental form II_p, consider a regular curve $C \subset S$ parametrized by $\alpha(s)$, where s is the arc length of C, and with $\alpha(0) = p$. If we denote by $N(s)$ the restriction of the normal vector N to the curve $\alpha(s)$, we have $\langle N(s), \alpha'(s)\rangle = 0$. Hence,

$$\langle N(s), \alpha''(s)\rangle = -\langle N'(s), \alpha'(s)\rangle.$$

Therefore,

$$\begin{aligned} II_p(\alpha'(0)) &= -\langle dN_p(\alpha'(0)), \alpha'(0)\rangle \\ &= -\langle N'(0), \alpha'(0)\rangle = \langle N(0), \alpha''(0)\rangle \\ &= \langle N, kn\rangle(p) = k_n(p). \end{aligned}$$

In other words, the value of the second fundamental form II_p for a unit vector $v \in T_p(S)$ is equal to the normal curvature of a regular curve passing through p and tangent to v. In particular, we obtained the following result.

PROPOSITION 2 (Meusnier). *All curves lying on a surface* S *and having at a given point* p ∈ S *the same tangent line have at this point the same normal curvatures.*

The above proposition allows us to speak of the *normal curvature along a given direction at p.* It is convenient to use the following terminology. Given a unit vector $v \in T_p(S)$, the intersection of S with the plane containing v and $N(p)$ is called the *normal section* of S at p along v (Fig. 3-9). In a neighborhood of p, a normal section of S at p is a regular plane curve on S whose normal vector n at p is $\pm N(p)$ or zero; its curvature is therefore equal to the absolute value of the normal curvature along v at p. With this terminology, the above

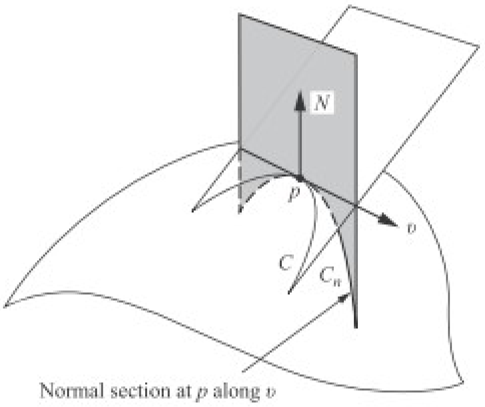

Figure 3-9. Meusnier theorem: C and C_n have the same normal curvature at p along v.

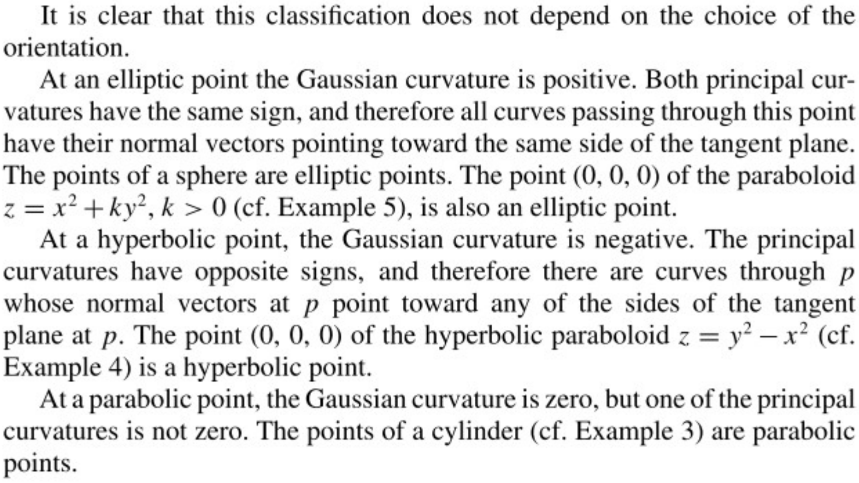
$$K = k_1 k_2, \quad H = \frac{k_1 + k_2}{2}.$$



It is clear that this classification does not depend on the choice of the orientation.

At an elliptic point the Gaussian curvature is positive. Both principal curvatures have the same sign, and therefore all curves passing through this point have their normal vectors pointing toward the same side of the tangent plane. The points of a sphere are elliptic points. The point (0, 0, 0) of the paraboloid $z = x^2 + ky^2$, $k > 0$ (cf. Example 5), is also an elliptic point.

At a hyperbolic point, the Gaussian curvature is negative. The principal curvatures have opposite signs, and therefore there are curves through p whose normal vectors at p point toward any of the sides of the tangent plane at p. The point (0, 0, 0) of the hyperbolic paraboloid $z = y^2 - x^2$ (cf. Example 4) is a hyperbolic point.

At a parabolic point, the Gaussian curvature is zero, but one of the principal curvatures is not zero. The points of a cylinder (cf. Example 3) are parabolic points.

4-3. The Gauss Theorem and the Equations of Compatibility

The properties of Chap. 3 were obtained from the study of the variation of the tangent plane in a neighborhood of a point. Proceeding with the analogy with curves, we are going to assign to each point of a surface a trihedron (the analogue of Frenet's trihedron) and study the derivatives of its vectors.

S will denote, as usual, a regular, orientable, and oriented surface. Let $\mathbf{x}\colon U \subset R^2 \to S$ be a parametrization in the orientation of S. It is possible to assign to each point of $\mathbf{x}(U)$ a natural trihedron given by the vectors $\mathbf{x}_u$, $\mathbf{x}_v$, and N. The study of this trihedron will be the subject of this section.

By expressing the derivatives of the vectors $\mathbf{x}_u, \mathbf{x}_v$, and N in the basis $\{\mathbf{x}_u, \mathbf{x}_v, N\}$, we obtain

$$\begin{aligned}
\mathbf{x}_{uu} &= \Gamma^1_{11}\mathbf{x}_u + \Gamma^2_{11}\mathbf{x}_v + L_1 N,\\
\mathbf{x}_{uv} &= \Gamma^1_{12}\mathbf{x}_u + \Gamma^2_{12}\mathbf{x}_v + L_2 N,\\
\mathbf{x}_{vu} &= \Gamma^1_{21}\mathbf{x}_u + \Gamma^2_{21}\mathbf{x}_v + \bar{L}_2 N,\\
\mathbf{x}_{vv} &= \Gamma^1_{22}\mathbf{x}_u + \Gamma^2_{22}\mathbf{x}_v + L_3 N,\\
N_u &= a_{11}\mathbf{x}_u + a_{21}\mathbf{x}_v,\\
N_v &= a_{12}\mathbf{x}_u + a_{22}\mathbf{x}_v,
\end{aligned} \tag{1}$$

where the a_{ij}, $i, j = 1, 2$, were obtained in Chap. 3 and the other coefficients are to be determined. The coefficients Γ^k_{ij}, $i, j, k = 1, 2$, are called the Christoffel symbols of S in the parametrization $\mathbf{x}$. Since $\mathbf{x}_{uv} = \mathbf{x}_{vu}$, we conclude that $\Gamma^1_{12} = \Gamma^1_{21}$ and $\Gamma^2_{12} = \Gamma^2_{21}$; that is, the *Christoffel symbols* are symmetric relative to the lower indices.

By taking the inner product of the first four relations in (1) with N, we immediately obtain $L_1 = e$, $L_2 = \bar{L}_2 = f$, $L_3 = g$, where e, f, g are the coefficients of the second fundamental form of S.

To determine the Christoffel symbols, we take the inner product of the first four relations with $\mathbf{x}_u$ and $\mathbf{x}_v$, obtaining the system

$$\begin{aligned}
&\begin{cases}
\Gamma^1_{11}E + \Gamma^2_{11}F = \langle \mathbf{x}_{uu}, \mathbf{x}_u\rangle = \frac{1}{2}E_u,\\
\Gamma^1_{11}F + \Gamma^2_{11}G = \langle \mathbf{x}_{uu}, \mathbf{x}_v\rangle = F_u - \frac{1}{2}E_v,
\end{cases}\\
&\begin{cases}
\Gamma^1_{12}E + \Gamma^2_{12}F = \langle \mathbf{x}_{uv}, \mathbf{x}_u\rangle = \frac{1}{2}E_v,\\
\Gamma^1_{12}F + \Gamma^2_{12}G = \langle \mathbf{x}_{uv}, \mathbf{x}_v\rangle = \frac{1}{2}G_u,
\end{cases}\\
&\begin{cases}
\Gamma^1_{22}E + \Gamma^2_{22}F = \langle \mathbf{x}_{vv}, \mathbf{x}_u\rangle = F_v - \frac{1}{2}G_u,\\
\Gamma^1_{22}F + \Gamma^2_{22}G = \langle \mathbf{x}_{vv}, \mathbf{x}_v\rangle = \frac{1}{2}G_v.
\end{cases}
\end{aligned} \tag{2}$$

Note that the above equations have been grouped into three pairs of equations and that for each pair the determinant of the system is $EG - F^2 \neq 0$.

Thus, it is possible to solve the above system and *to compute the Christoffel symbols in terms of the coefficients of the first fundamental form, E, F, G, and their derivatives.* We shall not obtain the explicit expressions of the $\mathbf{\Gamma}_{ij}^k$, since it is easier to work in each particular case with the system (2). (See Example 1 below.) However, the following consequence of the fact that we can solve the system (2) is very important: *All geometric concepts and properties expressed in terms of the Christoffel symbols are invariant under isometries.*

Example 1. We shall compute the Christoffel symbols for a surface of revolution parametrized by (cf. Example 4, Sec. 2-3)

$$\mathbf{x}(u, v) = \{f(v)\cos u, f(v)\sin u, g(v)), \quad f(v) \neq 0.$$

Since

$$E = (f(v))^2, \quad F = 0, \quad G = \{f'(v))^2 + (g'(v))^2,$$

we obtain

$$\begin{aligned} E_u &= 0, \qquad E_v = 2ff', \\ F_u &= F_v = 0, \quad G_u = 0, \\ G_v &= 2(f'f'' + g'g''), \end{aligned}$$

where prime denotes derivative with respect to v. The first two equations of the system (2) then give

$$\mathbf{\Gamma}_{11}^1 = 0, \quad \mathbf{\Gamma}_{11}^2 = -\frac{ff'}{(f')^2 + (g')^2}.$$

Next, the second pair of equations in system (2) yield

$$\mathbf{\Gamma}_{12}^1 = \frac{ff'}{f^2}, \quad \mathbf{\Gamma}_{12}^2 = 0.$$

Finally, from the last two equations in system (2) we obtain

$$\mathbf{\Gamma}_{22}^1 = 0, \quad \mathbf{\Gamma}_{22}^2 = \frac{f'f'' + g'g''}{(f')^2 + (g')^2}.$$

As we have just seen, the expressions of the derivatives of $\mathbf{x}_u$, $\mathbf{x}_v$, and N in the basis $\{x_u, \mathbf{x}_v, N\}$ involve only the knowledge of the coefficients of the first and second fundamental forms of S. A way of obtaining relations between these coefficients is to consider the expressions

$$\begin{aligned} (\mathbf{x}_{uu})_v - (\mathbf{x}_{uv})_u &= 0, \\ (\mathbf{x}_{vv})_u - (\mathbf{x}_{vu})_v &= 0, \\ N_{uv} - N_{vu} &= 0. \end{aligned} \tag{3}$$

By introducing the values of (1), we may write the above relations in the form

$$\begin{aligned} A_1\mathbf{x}_u + B_1\mathbf{x}_v + C_1 N &= 0, \\ A_2\mathbf{x}_u + B_2\mathbf{x}_v + C_2 N &= 0, \\ A_3\mathbf{x}_u + B_3\mathbf{x}_v + C_3 N &= 0, \end{aligned} \tag{3a}$$

where A_i, B_i, C_i, $i = 1, 2, 3$, are functions of E, F, G, e, f, g and of their derivatives. Since the vectors $\mathbf{x}_u, \mathbf{x}_v, N$ are linearly independent, (3a) implies that there exist nine relations:

$$A_i = 0, \quad B_i = 0, \quad C_i = 0, \quad i = 1, 2, 3.$$

As an example, we shall determine the relations $A_1 = 0$, $B_1 = 0$, $C_1 = 0$. By using the values of (1), the first of the relations (3) may be written

$$\begin{aligned} &\mathbf{\Gamma}_{11}^{1}\mathbf{x}_{uv} + \mathbf{\Gamma}_{11}^{2}\mathbf{x}_{vv} + eN_v + (\mathbf{\Gamma}_{11}^{1})_v\mathbf{x}_u + (\mathbf{\Gamma}_{11}^{2})_v\mathbf{x}_v + e_v N \\ &\quad = \mathbf{\Gamma}_{12}^{1}\mathbf{x}_{uu} + \mathbf{\Gamma}_{12}^{2}\mathbf{x}_{vu} + fN_u + (\mathbf{\Gamma}_{12}^{1})_u\mathbf{x}_u + (\mathbf{\Gamma}_{12}^{2})_u\mathbf{x}_v + f_u N. \end{aligned} \tag{4}$$

By using (1) again and equating the coefficients of $\mathbf{x}_v$, we obtain

$$\begin{aligned} &\mathbf{\Gamma}_{11}^{1}\mathbf{\Gamma}_{12}^{2} + \mathbf{\Gamma}_{11}^{2}\mathbf{\Gamma}_{22}^{2} + ea_{22} + (\mathbf{\Gamma}_{11}^{2})_v \\ &\quad = \mathbf{\Gamma}_{12}^{1}\mathbf{\Gamma}_{11}^{2} + \mathbf{\Gamma}_{12}^{2}\mathbf{\Gamma}_{12}^{2} + fa_{21} + (\mathbf{\Gamma}_{12}^{2})_u. \end{aligned}$$

Introducing the values of a_{ij} already computed (cf. Sec. 3-3) it follows that

$$\begin{aligned} (\mathbf{\Gamma}_{12}^{2})_u - (\mathbf{\Gamma}_{11}^{2})_v + \mathbf{\Gamma}_{12}^{1}\mathbf{\Gamma}_{11}^{2} + \mathbf{\Gamma}_{12}^{2}\mathbf{\Gamma}_{12}^{2} - \mathbf{\Gamma}_{11}^{2}\mathbf{\Gamma}_{22}^{2} - \mathbf{\Gamma}_{11}^{1}\mathbf{\Gamma}_{12}^{2} &\\ = -E\frac{eg - f^2}{EG - F^2} &\\ = -EK. & \end{aligned} \tag{5}$$

At this point it is convenient to interrupt our computations in order to draw attention to the fact that the above equation proves the following theorem, due to K. F. Gauss.

THEOREMA EGREGIUM (Gauss). *The Gaussian curvature* K *of a surface is invariant by local isometries.*

In fact if $\mathbf{x}\colon U \subset R^2 \to S$ is a parametrization at $p \in S$ and if $\varphi\colon V \subset S - \bar{S}$, where $V \subset \mathbf{x}(U)$ is a neighborhood of p, is a local isometry at p, then $y = \varphi \circ \mathbf{x}$ is a parametrization of $\bar{S}$ at $\varphi(p)$. Since φ is an isometry, the coefficients of the first fundamental form in the parametrizations $\mathbf{x}$ and $\mathbf{y}$ agree at corresponding points q and $\varphi(q)$, $q \in V$; thus, the corresponding Christoffel symbols also agree. By Eq. (5), K can be computed at a point as a function of the Christoffel symbols in a given parametrization at the point. It follows that $K(q) = K(\varphi(q))$ for all $q \in V$.

The above expression, which yields the value of K in terms of the coefficients of the first fundamental form and its derivatives, is known as the *Gauss formula.* It was first proved by Gauss in a famous paper [1].

The Gauss theorem is considered, by the extension of its consequences, one of the most important facts of differential geometry. For the moment we shall mention only the following corollary.

As was proved in Sec. 4-2, a catenoid is locally isometric to a helicoid. It follows from the Gauss theorem that the Gaussian curvatures are equal at corresponding points, a fact which is geometrically nontrivial.

Actually, it is a remarkable fact that a concept such as the Gaussian curvature, the definition of which made essential use of the position of a surface in the space, does not depend on this position but only on the metric structure (first fundamental form) of the surface.

We shall see in the next section that many other concepts of differential geometry are in the same setting as the Gaussian curvature; that is, they depend only on the first fundamental form of the surface. It thus makes sense to talk about a geometry of the first fundamental form, which we call intrinsic geometry, since it may be developed without any reference to the space that contains the surface (once the first fundamental form is given).

[†]With an eye to a further geometrical result we come back to our computations. By equating the coefficients of $\mathbf{x}_u$ in (4), we see that the relation $A_1 = 0$ may be written in the form

$$(\mathbf{\Gamma}^1_{12})_u - (\mathbf{\Gamma}^1_{11})_v + \mathbf{\Gamma}^2_{12}\mathbf{\Gamma}^1_{12} - \mathbf{\Gamma}^2_{11}\mathbf{\Gamma}^1_{22} = FK. \qquad \mathbf{(5a)}$$

By equating also in Eq. (4) the coefficients of N, we obtain $C_1 = 0$ in the form

$$e_v - f_u = e\mathbf{\Gamma}^1_{12} + f(\mathbf{\Gamma}^2_{12} - \mathbf{\Gamma}^1_{11}) - g\mathbf{\Gamma}^2_{11}. \qquad \mathbf{(6)}$$

Observe that relation (5a) is (when $F \neq 0$) merely another form of the Gauss formula (5).

By applying the same process to the second expression of (3), we obtain that both the equations $A_2 = 0$ and $B_2 = 0$ give again the Gauss formula (5). Furthermore, $C_2 = 0$ is given by

$$f_v - g_u = e\mathbf{\Gamma}^1_{22} + f(\mathbf{\Gamma}^2_{22} - \mathbf{\Gamma}^1_{12}) - g\mathbf{\Gamma}^2_{12}. \qquad \mathbf{(6a)}$$

Finally, the same process can be applied to the last expression of (3), yielding that $C_3 = 0$ is an identity and that $A_3 = 0$ and $B_3 = 0$ are again Eqs. (6) and (6a). Equations (6) and (6a) are called *Mainardi-Codazzi equations.*

[†] The rest of this section will not be used until Chap. 5. If omitted, Exercises 7 and 8 should also be omitted.

The Gauss formula and the Mainardi-Codazzi equations are known under the name of *compatibility equations* of the theory of surfaces.

A natural question is whether there exist further relations of compatibility between the first and the second fundamental forms besides those already obtained. The theorem stated below shows that the answer is negative. In other words, by successive derivations or any other process we would obtain no further relations among the coefficients E, F, G, e, f, g and their derivatives. Actually, the theorem is more explicit and asserts that the knowledge of the first and second fundamental forms determines a surface locally. More precisely,

THEOREM (Bonnet). *Let* E, F, G, e, f, g *be differentiable functions, defined in an open set* $\mathrm{V} \subset \mathrm{R}^2$, *with* $\mathrm{E} > 0$ *and* $\mathrm{G} > 0$. *Assume that the given functions satisfy formally the Gauss and Mainardi-Codazzi equations and that* $\mathrm{EG} - \mathrm{F}^2 > 0$. *Then, for every* $\mathrm{q} \in \mathrm{V}$ *there exists a neighborhood* $\mathrm{U} \subset \mathrm{V}$ *of* q *and a diffeomorphism* $\mathbf{x}\colon \mathrm{U} \to \mathbf{x}(\mathrm{U}) \subset \mathrm{R}^3$ *such that the regular surface* $\mathbf{x}(\mathrm{U}) \subset \mathrm{R}^3$ *has* E, F, G *and* e, f, g *as coefficients of the first and second fundamental forms, respectively. Furthermore, if* U *is connected and if*

$$\bar{\mathrm{x}}\colon \mathrm{U} \to \bar{\mathrm{x}}(\mathrm{U}) \subset \mathrm{R}^3$$

is another diffeomorphism satisfying the same conditions, then there exist a translation T *and a proper linear orthogonal transformation* ρ *in* R^3 *such that* $\bar{\mathrm{x}} = \mathrm{T} \circ \rho \circ \mathbf{x}$.

A proof of this theorem may be found in the appendix to Chap. 4.

For later use, it is convenient to observe how the Mainardi-Codazzi equations simplify when the coordinate neighborhood contains no umbilical points and the coordinate curves are lines of curvature ($F = 0 = f$). Then, Eqs. (6) and (6a) may be written

$$e_v = e\mathbf{\Gamma}^1_{12} - g\mathbf{\Gamma}^2_{11}, \quad g_u = g\mathbf{\Gamma}^2_{12} - e\mathbf{\Gamma}^1_{22}.$$

By taking into consideration that $F = 0$ implies that

$$\mathbf{\Gamma}^2_{11} = -\frac{1}{2}\frac{E_v}{G}, \quad \mathbf{\Gamma}^1_{12} = \frac{1}{2}\frac{E_v}{E},$$
$$\mathbf{\Gamma}^1_{22} = -\frac{1}{2}\frac{G_u}{E}, \quad \mathbf{\Gamma}^2_{12} = \frac{1}{2}\frac{G_u}{G},$$

we conclude that the Mainardi-Codazzi equations take the following form:

$$e_v = \frac{E_v}{2}\left(\frac{e}{E} + \frac{g}{G}\right), \tag{7}$$

$$g_u = \frac{G_u}{2}\left(\frac{e}{E} + \frac{g}{G}\right). \tag{7a}$$

4-4. Parallel Transport. Geodesics.

We shall now proceed to a systematic exposition of the intrinsic geometry. To display the intuitive meaning of the concepts, we shall often give definitions and interpretations involving the space exterior to the surface. However, we shall prove in each case that the concepts to be introduced depend only on the first fundamental form.

We shall start with the definition of covariant derivative of a vector field, which is the analogue for surfaces of the usual differentiation of vectors in the plane. We recall that a *(tangent) vector field* in an open set $U \subset S$ of a regular surface S is a correspondence w that assigns to each $p \in U$ a vector $w(p) \in T_p(S)$. The vector field w is *differentiable* at p if, for some parametrization $\mathbf{x}(u, v)$ in p, the components a and b of $w = a\mathbf{x}_u + b\mathbf{x}_v$ in the basis $\{\mathbf{x}_u, \mathbf{x}_v\}$ are differentiable functions at p. The vector field w is differentiable in U if it is differentiable for every $p \in U$.

DEFINITION 1. *Let* w *be a differentiable vector field in an open set* $\mathrm{U} \subset \mathrm{S}$ *and* $\mathrm{p} \in \mathrm{U}$. *Let* $\mathrm{y} \in \mathrm{T_p(S)}$. *Consider a parametrized curve*

$$\alpha\colon (-\epsilon, \epsilon) \to \mathrm{U},$$

with $\alpha(0) = \mathrm{p}$ *and* $\alpha'(0) = \mathrm{y}$, *and let* $\mathrm{w(t)}$, $\mathrm{t} \in (-\epsilon, \epsilon)$, *be the restriction of the vector field* w *to the curve* α. *The vector obtained by the normal projection of* $(\mathrm{dw/dt})(0)$ *onto the plane* $\mathrm{T_p(S)}$ *is called the* covariant derivative *at* p *of the vector field* w *relative to the vector* y. *This covariant derivative is denoted by* $(\mathrm{Dw/dt})(0)$ *or* $(\mathrm{D_y w})(\mathrm{p})$ *(Fig. 4-8).*

The above definition makes use of the normal vector of *S* and of a particular curve α, tangent to y at p. To show that covariant differentiation is a concept

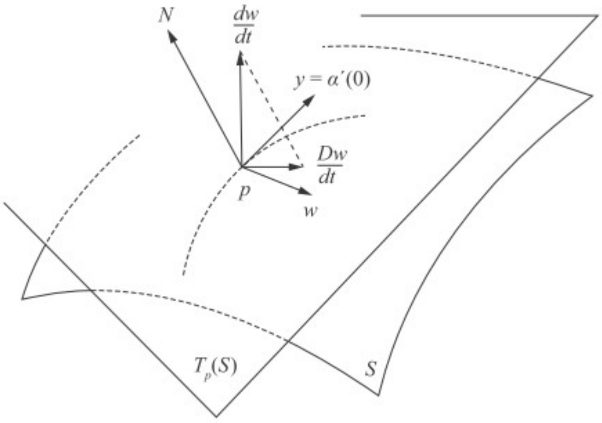

Figure 4-8. The covariant derivative.

b. If θ, $0 \leq \theta \leq \pi/2$, is the angle which a geodesic makes with the curve $v = \text{const.}$, then

$$U \sin^2\theta - V \cos^2\theta = \text{const.}$$

(Notice that this is the analogue of Clairaut's relation for the surfaces of Liouville.)

22. Let $S^2 = \{(x, y, z) \in R^3; x^2 + y^2 + z^2 = 1\}$ and let $p \in S^2$. For each piecewise regular parametrized curve $\alpha\colon [0, l] \to S^2$ with $\alpha(0) = \alpha(l) = p$, let $P_\alpha\colon T_p(S^2) \to T_p(S^2)$ be the map which assigns to each $v \in T_p(S^2)$ its parallel transport along α back to p. By Prop. 1, P_α is an isometry. Prove that for every rotation R of $T_p(S)$ there exists an α such that $R = P_\alpha$.

23. Show that the isometries of the unit sphere

$$S^2 = \{(x, y, z) \in R^3; x^2 + y^2 + z^2 = 1\}$$

are the restrictions to S^2 of the linear orthogonal transformations of R^3.

4-5. The Gauss-Bonnet Theorem and Its Applications

In this section, we shall present the Gauss-Bonnet theorem and some of its consequences. The geometry involved in this theorem is fairly simple, and the difficulty of its proof lies in certain topological facts. These facts will be presented without proofs.

The Gauss-Bonnet theorem is probably the deepest theorem in the differential geometry of surfaces. A first version of this theorem was presented by Gauss in a famous paper [1] and deals with geodesic triangles on surfaces (that is, triangles whose sides are arcs of geodesics). Roughly speaking, it asserts that the excess over π of the sum of the interior angles $\varphi_1, \varphi_2, \varphi_3$ of a geodesic triangle T is equal to the integral of the Gaussian curvature K over T; that is (Fig. 4-23),

$$\sum_{i=1}^{3} \varphi_i - \pi = \iint_T K\,d\sigma.$$

For instance, if $K \equiv 0$, we obtain that $\sum \varphi_i = \pi$, an extension of Thales' theorem of high school geometry to surfaces of zero curvature. Also, if $K \equiv 1$, we obtain that $\sum \varphi_i - \pi = \text{area }(T) > 0$. Thus, on a unit sphere, the sum of the interior angles of any geodesic triangle is greater than π, and the excess over π is exactly the area of T. Similarly, on the pseudosphere (Exercise 6, Sec. 3-3) the sum of the interior angles of any geodesic triangle is smaller than π (Fig. 4-24).

Figure 4-24

The extension of the theorem to a region bounded by a nongeodesic simple curve (see Eq. (1) below) is due to O. Bonnet. To extend it even further, say, to compact surfaces, some topological considerations will come into play. Actually, one of the most important features of the Gauss-Bonnet theorem is that it provides a remarkable relation between the topology of a compact surface and the integral of its curvature (see Corollary 2 below).

We shall now begin the details of a local version of the Gauss-Bonnet theorem. We need a few definitions.

Let $\alpha\colon [0, l] \to S$ be a continuous map from the closed interval $[0, l]$ into the regular surface S. We say that α is a *simple, closed, piecewise regular, parametrized curve if*

1. $\alpha(0) = \alpha(l)$.
2. $t_1 \neq t_2, t_1, t_2 \in [0, l)$, implies that $\alpha(t_1) \neq \alpha(t_2)$.

3. There exists a subdivision

$$0 = t_0 < t_1 < \cdots < t_k < t_{k+1} = l,$$

of $(0, l]$ such that α is differentiable and regular in each (t_i, t_{i+1}), $i = 0, \dots, k$.

Intuitively, this means that α is a closed curve (condition 1) without self-intersections (condition 2), which fails to have a well-defined tangent line only at a finite number of points (condition 3).

The points $\alpha(t_i)$, $i = 0, \dots, k$, are called the *vertices* of α and the traces $\alpha([t_i, t_{i+1}])$ are called the *regular arcs* of α. It is usual to call the trace $\alpha([0, l])$ of α, a *closed piecewise regular curve*.

By the condition of regularity, for each vertex $\alpha(t_i)$ there exist the limit from tile left, i.e., for $t < t_i$

$$\lim_{t \to t_i} \alpha'(t) = \alpha'(t_i - 0) \neq 0,$$

and the limit from the right, i.e., for $t > t_i$,

$$\lim_{t \to t_i} \alpha'(t) = \alpha'(t_i + 0) \neq 0.$$

Assume now that S is oriented and let $|\theta_i|$, $0 \leq |\theta_i| < \pi$, be the smallest determination of the angle from $\alpha'(t_i - 0)$ to $\alpha'(t_i + 0)$. If $|\theta_i| \neq \pi$, we give θ_i the sign of the determinant $(\alpha'(t_i - 0), \alpha'(t_i + 0), N)$. This means that if the vertex $\alpha(t_i)$ is not a "cusp" (Fig. 4-25), the sign of θ_i is given by the orientation of S. The signed angle θ_i, $-\pi < \theta_i < \pi$, is called the *external angle* at the vertex $\alpha(t_i)$.

In the case that $\alpha(t_i)$ is a cusp, i.e., $|\theta_i| = \pi$, we choose the sign of θ_i as follows. Let the closed simple curve α be contained in the image of a conformal parametrization with a given orientation, and assume that $\alpha(t_i)$ is a cusp. Choose coordinate axis $x0y$, with $\alpha(t_i) = 0$, in the given orientation,

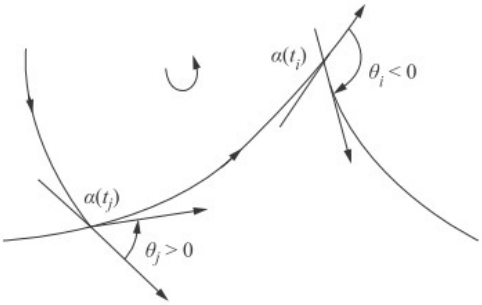

Figure 4-25

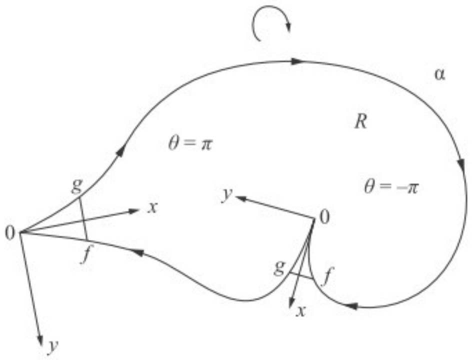

Figure 4-26. The sign of the external angle in the case of a cusp.

and assume further that the part of α arriving at $\alpha(t_i)$ is pointing towards the negative part of the axis $0x$ (and, of course, the part of α leaving $\alpha(t_i)$ is pointing to the positive part of the axis $0x$).

For small $\varepsilon > 0$, the part of α arriving at $\alpha(t_i)$, and near it, is given by a function $f(x) = y$, $0 < x < \epsilon$, and the part of α leaving t_i, and near it, is given by a function $g(x) = y$, $0 < x < \epsilon$. If $f > 0$ and $g < 0$, we set $\theta(t_i) = \pi$ and if $f < 0$ and $g > 0$, we set $\theta(t_i) = -\pi$.

This settles the question of the angle at a cusp.

Let α: $[0, l] \to \mathbf{x}(U) \subset S$ be a simple closed, piecewise regular, parametrized curve, with vertices $\alpha(t_i)$ and external angles θ_i, $i = 0, \dots, k$.

Let φ_i: $[t_i, t_{i+1}] \to R$ be differentiable functions which measure at each $t \in [t_i, t_{i+1}]$ the positive angle from $\mathbf{x}_u$ to $\alpha'(t)$ (cf. Lemma 1, Sec. 4-4).

The first topological fact that we shall present without proofs is the following.

THEOREM (of Turning Tangents). *With the above notation we have for plane curves*

$$\sum_{i=0}^{k}(\varphi_i(t_{i+1}) - \varphi_i(t_i)) + \sum_{i=0}^{k}\theta_i = \pm 2\pi,$$

where the sign plus or minus depends on the orientation of α.

The theorem states that the total variation of the angle of the tangent vector to α with a given direction plus the "jumps" at the vertices is equal to 2π.

An elegant proof of this theorem has been given by H. Hopf, *Compositio Math.* 2 (1935), 50–62. For the case where α has no vertices, Hopf's proof can be found in Sec. 5-7 (Theorem 2) of this book. It should be noted that Hopf's proof is for plane curves.

Before stating the local version of the Gauss-Bonnet theorem we still need some terminology.

Let S be an oriented surface. A region $R \subset S$ (union of a connected open set with its boundary) is called a *simple region* if R is homeomorphic to a disk and the boundary ∂R of R is the trace of a simple, closed, piecewise regular, parametrized curve $\alpha\colon I \to S$. We say then that α is *positively oriented* if for each $\alpha(t)$, belonging to a regular arc, the positive orthogonal basis $\{\alpha'(t), h(t)\}$ satisfies the condition that $h(t)$ "points toward" R; more precisely, for any curve $\beta\colon I \to R$ with $\beta(0) = \alpha(t)$ and $\beta'(0) \neq \alpha'(t)$, we have that $\langle \beta'(0), h(t)\rangle > 0$. Intuitively, this means that if one is walking on the curve α in the positive direction and with one's head pointing to N, then the region R remains to the left (Fig. 4-27). It can be shown that one of the two possible orientations of α makes it positively oriented.

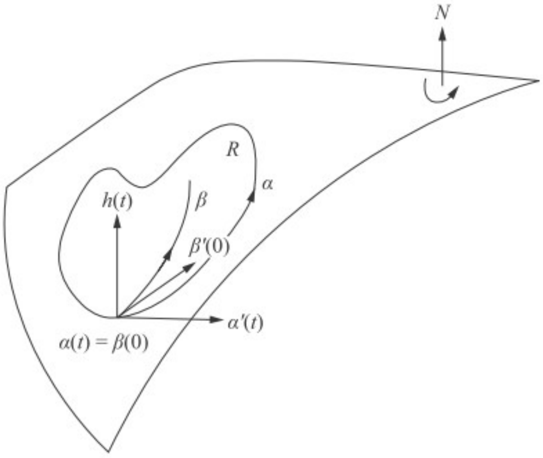

Figure 4-27. A positively oriented boundary curve.

Now let $\mathbf{x}\colon U \subset R^2 \to S$ be a parametrization of S compatible with its orientation and let $R \subset \mathbf{x}(U)$ be a bounded region of S. If f is a differentiable function on S, then it is easily seen that the integral

$$\iint_{\mathbf{x}^{-1}(R)} f(u, v)\sqrt{EG - F^2}\, du\, dv$$

does not depend on the parametrization $\mathbf{x}$, chosen in the class of orientation of $\mathbf{x}$. (The proof is the same as in the definition of area; cf. Sec. 2-5.) This integral has, therefore, a geometrical meaning and is called *the integral of f over the region R*. It is usual to denote it by

$$\iint_R f\, d\sigma.$$

With these definitions, we now state the

GAUSS-BONNET THEOREM (Local). *Let* $\mathbf{x}$: U $\to$ S *be an isothermal parametrization (i.e.,* $F = 0$, $E = G = \lambda^2(u, v)$*). See Sec. 4.2 after Prop. 2) of an oriented surface* S, *where* U $\subset$ R^2 *is homeomorphic to an open disk and* $\mathbf{x}$ *is compatible with the orientation of* S.

Let R $\subset$ $\mathbf{x}$(U) *be a simple region of* S *and let* α: $I \to S$ *be such that* ∂R $= \alpha$(I). *Assume that* α *is positively oriented, parametrized by arc length* s, *and let* $\alpha(\mathrm{s}_0), \ldots, \alpha(\mathrm{s}_\mathrm{k})$ *and* $\theta_0, \ldots, \theta_\mathrm{k}$ *be, respectively, the vertices and the external angles of* α. *Then*

$$\sum_{\mathrm{i}=0}^{\mathrm{k}} \int_{\mathrm{s}_\mathrm{i}}^{\mathrm{s}_{\mathrm{i}+1}} \mathrm{k}_\mathrm{g}(\mathrm{S})\, \mathrm{ds} + \iint_\mathrm{R} \mathrm{K}\, \mathrm{d}\sigma + \sum_{\mathrm{i}=0}^{\mathrm{k}} \theta_\mathrm{i} = 2\pi, \qquad \mathbf{(1)}$$

where $\mathrm{k}_\mathrm{g}(\mathrm{s})$ *is the geodesic curvature of the regular arcs of* α *and* K *is the Gaussian curvature of* S.

Remark. The restriction that the region *R* be contained in the image set of an isothermal parametrization is needed only to simplify the proof and to be able to use the theorem of turning tangents. As we shall see later (Corollary 1 of the global Gauss-Bonnet theorem) the above result still holds for any simple region of a regular surface. This is quite plausible, since Eq. (1) does not involve in any way a particular parametrization.[†]

Proof. Let $u = u(s)$, $v = v(s)$ be the expression of α in the parametrization $\mathbf{x}$. By using Prop. 3 of Sec. 4-4, we have

$$k_g(s) = \frac{1}{2\sqrt{EG}}\left\{G_u \frac{dv}{ds} - E_v \frac{du}{ds}\right\} + \frac{d\varphi_i}{ds},$$

where $\varphi_i = \varphi_i(s)$ is a differentiable function which measures the positive angle from $\mathbf{x}_u$ to $\alpha'(s)$ in $[s_i, s_{i+1}]$. By integrating the above expression in every interval $[s_i, s_{i+1}]$ and adding up the results,

$$\sum_{i=0}^{k} \int_{s_i}^{s_{i+1}} k_g(s)\, ds = \sum_{i=0}^{k} \int_{s_i}^{s_{i+1}} \left(\frac{G_u}{2\sqrt{EG}} \frac{dv}{ds} - \frac{E_v}{2\sqrt{EG}} \frac{du}{ds}\right) ds$$
$$+ \sum_{i=0}^{k} \int_{s_i}^{s_{i+1}} \frac{d\varphi_i}{ds}\, ds.$$

Now we use the Gauss-Green theorem in the uv plane which states the following: *If* $P(u, v)$ *and* $Q(u, v)$ *are differentiable functions in a simple region* $A \subset R^2$, *tire boundary of which is given by* $u = u(s)$, $v = v(s)$, *then*

[†] If the truth of this assertion is assumed, applications 2 and 6 given below can be presented now.

$$\sum_{i=0}^{k}\int_{s_i}^{s_{i+1}}\left(P\frac{du}{ds}+Q\frac{dv}{ds}\right)ds=\iint_A\left(\frac{\partial Q}{\partial u}-\frac{\partial P}{\partial v}\right)du\,dv.$$

It follows that

$$\sum_{i=0}^{k}\int_{s_i}^{s_{i+1}}k_g(s)\,ds=\iint_{\mathbf{x}^{-1}(R)}\left\{\left(\frac{E_v}{2\sqrt{EG}}\right)_v+\left(\frac{G_u}{2\sqrt{EG}}\right)_u\right\}du\,dv$$
$$+\sum_{i=0}^{k}\int_{s_i}^{s_{i+1}}\frac{d\varphi_i}{ds}\,ds.$$

To be able to use the theorem of turning tangents, we must assume that our parametrization is isothermal, that is, in addition to $F=0$, we have that $E=G=\lambda(u,v)>0$. In this case,

$$\begin{aligned}\left(\frac{E_v}{2\sqrt{EG}}\right)_v+\left(\frac{G_u}{2\sqrt{EG}}\right)_u&=\frac{1}{2}\left\{\left(\frac{\lambda_v}{\lambda}\right)_v+\left(\frac{\lambda_u}{\lambda}\right)_u\right\}\\&=\frac{1}{2\lambda}\{(\log\lambda)_{vv}+(\log\lambda)_{uu}\}\lambda\\&=\frac{1}{2\lambda}(\Delta\log\lambda)\lambda=-K\lambda,\end{aligned}$$

where, in the last equality we have used the Exercise 2 of Section 4-3. By integrating the above expression in the domain of the coordinate neighborhood, we obtain

$$\sum_{i=0}^{k}\int_{s_i}^{s_{i+1}}k_g(s)\,ds=-\iint_R K\lambda\,du\,dv+\sum_i\int_{s_i}^{s_{i+1}}\frac{d\varphi_i}{ds}\,ds$$

On the other hand, by the theorem of turning tangents,

$$\begin{aligned}\sum_{i=0}^{k}\int_{s_i}^{s_{i+1}}\frac{d\varphi_i}{ds}\,ds&=\sum_{i=0}^{k}(\varphi_i(s_{i+1})-\varphi_i(s_i))\\&=\pm2\pi-\sum_{i=0}^{k}\theta_i.\end{aligned}$$

Since the curve α is positively oriented, the sign should be plus, as can easily be seen in the particular case of the circle in a plane.

By putting these facts together, we obtain

$$\sum_{i=0}^{k}\int_{s_i}^{s_{i+1}}k_g(s)\,ds+\iint_R K\,d\sigma+\sum_{i=0}^{k}\theta_i=2\pi.$$ **Q.E.D.**

Before going into a global version of the Gauss-Bonnet theorem, we would like to show how the techniques used in the proof of this theorem may also be used to give an interpretation of the Gaussian curvature in terms of parallelism.

To do that, let $\mathbf{x}: U \to S$ be an isothermal parametrization at a point $p \in S$, and let $R \subset \mathbf{x}(U)$ be a simple region without vertices, containing p in its interior. Let $\alpha: [0, l] \to \mathbf{x}(U)$ be a curve parametrized by arc length s such that the trace of α is the boundary of R. Let w_0 be a unit vector tangent to S at $\alpha(0)$ and let $w(s)$, $s \in [0, l]$, be the parallel transport of w_0 along α (Fig. 4-28). By using Prop. 3 of Sec. 4-4 and the Gauss-Green theorem in the uv plane, we obtain

$$\begin{aligned} 0 &= \int_0^l \left[\frac{Dw}{ds}\right] ds \\ &= \int_0^l \frac{1}{2\sqrt{EG}} \left\{ G_u \frac{dv}{ds} - E_v \frac{du}{ds} \right\} ds + \int_0^l \frac{d\varphi}{ds}\, ds \\ &= -\iint_R K\, d\sigma + \varphi(l) - \varphi(0), \end{aligned}$$

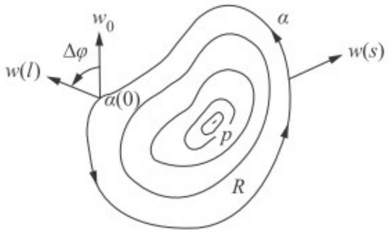

Figure 4-28

where $\varphi = \varphi(s)$ is a differentiable determination of the angle from $\mathbf{x}_u$ to $w(s)$. It follows that $\varphi(l) - \varphi(0) = \Delta\varphi$ is given by

$$\Delta\varphi = \iint_R K\, d\sigma. \tag{2}$$

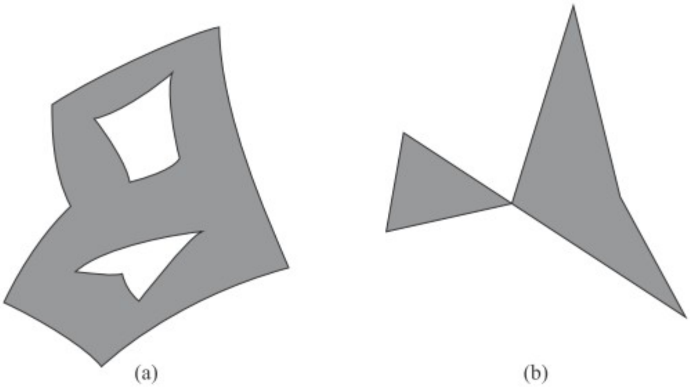
Now, $\Delta\varphi$ does not depend on the choice of w_0, and it follows from the expression above that $\Delta\varphi$ does not depend on the choice of $\alpha(0)$ either. By taking the limit (in the sense of Prop. 2, Sec. 3-3)

$$\lim_{R \to p} \frac{\Delta\varphi}{A(R)} = K(p),$$

where $A(R)$ denotes the area of the region R, we obtain the desired interpretation of K.

To globalize the Gauss-Bonnet theorem, we need further topological preliminaries.

Let S be a regular surface. A connected region $R \subset S$ is said to be *regular* if R is compact and its boundary ∂R is the finite union of (simple) closed piecewise regular curves which do not intersect (the region in Fig. 4-29(a) is regular, but that in Fig. 4-29(b) is not). For convenience, we shall consider a compact surface as a regular region, the boundary of which is empty.



(a) (b)

Figure 4-29

A simple region which has only three vertices with external angles $\alpha_i \neq 0$, $i = l, 2, 3$, is called a *triangle*.

A *triangulation* of a regular region $R \subset S$ is a finite family $\mathfrak{J}$ of triangles $T_i, = 1, \dots, n$, such that

1. $\bigcup_{i=1}^{n} T_i = R$.
2. If $T_i \cap T_j \neq \phi$, then $T_i \cap T_j$ is either a common edge of T_i and T_j or a common vertex of T_i and T_j.

Given a triangulation $\mathfrak{J}$ of a regular region $R \subset S$ of a surface S, we shall denote by F the number of triangles (faces), by E the number of sides (edges), and by V the number of vertices of the triangulation. The number

$$F - E + V = \chi$$

is called the *Euler-Poincaré characteristic* of the triangulation.

The following propositions are presented without proofs. An exposition of these facts may be found, for instance, in L. Ahlfors and L. Sario, *Riemann Surfaces*, Princeton University Press, Princeton, N.J., 1960, Chap. 1.

PROPOSITION 1. *Every regular region of a regular surface admits a triangulation.*

% RRR

5- 662 N 3

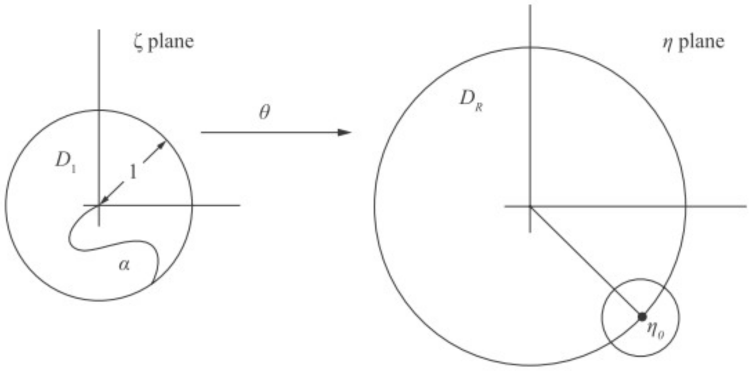


Figure 5-12

Let L be the segment of D_R that joins η_0 to 0; i.e., $L = \{t\eta_0 \in \mathbb{C}; 0 \leq t \leq 1\}$. Set $\alpha = \theta^{-1}(L)$ and show that the arc length l of $\mathbf{x}(\alpha)$ is

$$\begin{aligned} l &= \int_\alpha \sqrt{2\langle \mathbf{x}_u, \mathbf{x}_v\rangle \left\{ \left(\frac{du}{dt}\right)^2 + \left(\frac{dv}{dt}\right)^2 \right\}}\,dt \\ &\leq \frac{1}{\epsilon}\int_\alpha \sqrt{\langle \mathbf{x}_u, w\rangle^2 + \langle \mathbf{x}_v, w\rangle^2}\,|d\zeta| = \frac{1}{\epsilon}\int_\alpha |\varphi(\zeta)||d\zeta| \\ &= \frac{R}{\epsilon} < +\infty. \end{aligned}$$

Use Exercise 7 to conclude that $\mathbf{x}(D)$ is not complete.

5-4. First and Second Variations of Arc Length; Bonnet's Theorem

The goal of this section is to prove that a complete surface S with Gaussian curvature $K \geq \delta > 0$ is compact (Bonnet's theorem).

The crucial point of the proof is to show that if $K \geq \delta > 0$, a geodesic γ joining two arbitrary points $p, q \in S$ and having length $l(\gamma) > \pi/\sqrt{\delta}$ is no longer minimal; that is, there exists a parametrized curve joining p and q, the length of which is smaller than $l(\gamma)$.

Once this is proved, it follows that every minimal geodesic has length $l \leq \pi/\sqrt{\delta}$; thus, S is bounded in the distance d. Since S is complete, S is compact (Corollary 2, Sec. 5-3). We remark that, in addition, we obtain an estimate for the diameter of S, namely, $\rho(S) \leq \pi/\sqrt{\delta}$.

To prove the above point, we need to compare the arc length of a parametrized curve with the arc length of "neighboring curves." For this, we shall introduce a number of ideas which are useful in other problems of differential geometry. Actually, these ideas are adaptations to the purposes of differential geometry of more general concepts found in calculus of variations. No knowledge of calculus of variations will be assumed.

In this section, S will denote a regular (not necessarily complete) surface.

We shall begin by making precise the idea of neighboring curves of a given curve.

DEFINITION 1. *Let* α: $[0, l] \to \mathrm{S}$ *be a regular parametrized curve, where the parameter* $\mathrm{s} \in [0, l]$ *is the arc length. A variation of* α *is a differentiable map* h: $[0, l] \times (-\epsilon, \epsilon) \subset \mathrm{R}^2 \to \mathrm{S}$ *such that*

$$\mathrm{h}(\mathrm{s}, 0) = \alpha(\mathrm{s}), \quad \mathrm{s} \in (0, l].$$

For each $\mathrm{t} \subset (-\epsilon, \epsilon)$*, the curve* $\mathrm{h_t}$: $[0, l] \to \mathrm{S}$*, given by* $\mathrm{h_t}(s) = \mathrm{h}(\mathrm{s}, \mathrm{t})$*, is called a curve of the variation* h. *A variation* h *is said to be proper if*

$$\mathrm{h}(0, \mathrm{t}) = \alpha(0), \quad \mathrm{h}(l, \mathrm{t}) = \alpha(l), \quad \mathrm{t} \in (-\epsilon, \epsilon).$$

Intuitively, a variation of α is a family h_t of curves depending differentiably on a parameter $t \in (-\epsilon, \epsilon)$ and such that h_0 agrees with α (Fig. 5-13). The condition of being proper means that all curves h_t have the same initial point $\alpha(0)$ and the same end point $\alpha(l)$.

It is convenient to adopt the following notation. The parametrized curves in R^2 given by

$$s \to (s, t_0),$$
$$t \to (s_0, t),$$

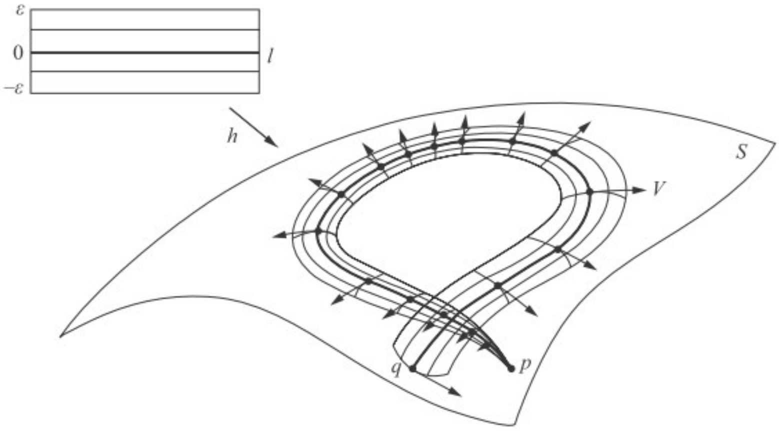

Figure 5-13

pass through the point $p_0 = (s_0, t_0) \in R^2$ and have $(1, 0)$ and $(0, 1)$ as tangent vectors at (s_0, t_0). Let h: $[0, l] \times (-\epsilon, \epsilon) \subset R^2 \to S$ be a differentiable map and let $p_0 \in [0, l] \times (-\epsilon, \epsilon)$. Then $dh_{p_0}(1, 0)$ is the tangent vector to the curve $s \to h(s, t_0)$ at $h(p_0)$, and $dh_{p_0}(0, 1)$ is the tangent vector to the curve $t \to h(s_0, t)$ at $h(p_0)$. We shall denote

$$dh_{p_0}(1, 0) = \frac{\partial h}{\partial s}(p_0),$$
$$dh_{p_0}(0, 1) = \frac{\partial h}{\partial t}(p_0).$$

We recall (cf. Sec. 4-4, Def. 3) that a vector field w along a curve α: $I \to S$ is a correspondence that assigns to each $t \in I$ a vector $w(t)$ *tangent to the surface* S at $\alpha(t)$. Thus, $\partial h/\partial s$ and $\partial h/\partial t$ are differentiable tangent vector fields along α.

It follows that a variation h of α determines a differentiable vector field $V(s)$ along α by

$$V(s) = \frac{\partial h}{\partial t}(s, 0), \quad S \in [0, l].$$

V is called the *variational vector field* of h; we remark that if h is proper, then

$$V(0) = V(l) = 0.$$

This terminology is justified by the following proposition.

PROPOSITION 1. *If we let* V(s) *be a differentiable vector field along a parametrized regular curve* α: $[0, l] \to$ S *then there exists a variation* h: $[0, l] \times (-\epsilon, \epsilon) \to$ S *of* α *such that* V(s) *is the variational vector field of* h. *Furthermore, if* $\mathrm{V}(0) = \mathrm{V}(l) = 0$*, then* h *can be chosen to be proper.*

Proof. We first show that there exists a $\delta > 0$ such that if $|v| < \delta$, $v \in T_{\alpha(s)}(S)$, then $\exp_{\alpha(s)} v$ is well defined for all $s \in [0, l]$. In fact, for each $p \in \alpha([0, l]) \subset S$ consider the neighborhood W_p (a normal neighborhood of all of its points) and the number $\delta_p > 0$ given by Prop. 1 of Sec. 4-7. The union $\bigcup_p W_p$ covers $\alpha([0, l])$ and, by compactness, a finite number of them, say, $W_1, \dots, W_n$ still covers $\alpha([0, l])$. Set $\delta = \min(\delta_1, \dots, \delta_n)$, where δ_i is the number corresponding to the neighborhood W_i, $i = 1, \dots, n$. It is easily seen that δ satisfies the above condition.

Now let $M = \max_{s \in [0,l]} |V(s)|$, $\epsilon < \delta/M$, and define

$$h(s, t) = \exp_{\alpha(t)} tV(s), \quad s \in [0, l], \quad t \in (-\epsilon, \epsilon).$$

h is clearly well defined. Furthermore, since

$$\exp_{\alpha(s)} tV(s) = \gamma(1, \alpha(s), tV(s)),$$

where γ is the (differentiable) map of Theorem 1 of Sec. 4-7 (i.e., for $t \neq 0$, and $V(s) \neq 0$, $\gamma(1, \alpha(s), tV(s))$ is the geodesic γ with initial conditions

5- < 26 <3

Remark 1. It should be noticed that the curvature condition $K \leq 0$ was used only to guarantee that $\exp_p : T_p(S) \to S$ is a length-increasing local diffeomorphism. Therefore, we have actually proved that *if* $\varphi\colon S_1 \to S_2$ *is a local diffeomorphism of a complete surface* S_1 *onto a surface* S_2, *which is length-increasing, then* φ *is a covering map.*

The following proposition, known as the Hadamard theorem, describes the topological structure of a complete surface with curvature $K \leq 0$.

THEOREM 1 (Hadamard). *Let* S *be a simply connected, complete surface, with Gaussian curvature* $K \leq 0$. *Then* $\exp_p\colon T_p(S) \to S$, $p \in S$, *is a diffeomorphism; that is,* S *is diffeomorphic to a plane.*

Proof. By Prop. 7, $\exp_p : T_p(S) \to S$ is a covering map. By the corollary of Prop. 5, $\exp_p$ is a homeomorphism. Since $\exp_p$ is a local diffeomorphism, its inverse map is differentiable, and $\exp_p$ is a diffeomorphism. **Q.E.D.**

We shall now present another geometric application of the covering spaces, also known as the Hadamard theorem. Recall that a connected, compact, regular surface, with Gaussian curvature $K > 0$, is called an ovaloid (cf. Remark 2, Sec. 5-2).

THEOREM 2 (Hadamard). *Let* S *be an ovaloid. Then the Gauss map* $N\colon S \to S^2$ *is a dijfepmorphism. In particular,* S *is diffeomorphic to a sphere.*

Proof. Since for every $p \in S$ the Gaussian curvature of S, $K = \det(dN_p)$, is positive, N is a local diffeomorphism. By Prop. 1, N is a covering map. Since the sphere S^2 is simply connected, we conclude from the corollary of Prop. 5 that $N\colon S \to S^2$ is a homeomorphism of S onto the unit sphere S^2. Since N is a local diffeomorphism, its inverse map is differentiable. Therefore, N is a diffeomorphism. **Q.E.D.**

Remark 2. Actually, we have proved somewhat more. Since the Gauss map N is a diffeomorphism, each unit vector v of R^3 appears exactly once as a unit normal vector to S. Taking a plane normal to v, away from the surface, and displacing it parallel to itself until it meets the surface, we conclude that S lies on one side of each of its tangent planes. This is expressed by saying that an ovaloid S is *locally convex*. It can be proved from this that S is actually the boundary of a convex set (that is, a set $K \subset R^3$ such that the line segment joining any two points $p, q \in K$ belongs entirely to K).

Remark 3. The fact that compact surfaces with $K > 0$ are homeomorphic to spheres was extended to compact surfaces with $K \geq 0$ by S. S. Chern and R. K. Lashof ("On the Total Curvature of Immersed Manifolds," *Michigan Math. J.* 5 (1958), 5–12). A generalization for complete surfaces was first obtained by J. J. Stoker ("Über die Gestalt der positiv gekrümnten offenen

Fläche," *Compositio Math.* 3 (1936), 58–89), who proved, among other things, the following: *A complete surface with $K > 0$ is homeomorphic to a sphere or a plane*. This result still holds for $K \geq 0$ if one assumes that at some point $K > 0$ (for a proof and a survey of this problem, see M. do Carmo and E. Lima, "Isometric Immersions with Non-negative Sectional Curvatures," *Boletim da Soc. Bras. Mat.* 2 (1971), 9–22).

EXERCISES

1. Show that the map $\pi\colon R \to S^1 = \{(x, y) \in R^2; x^2 + y^2 = 1\}$ that is given by $\pi(t) = (\cos t, \sin t)$, $t \in R$, is a covering map.

2. Show that the map $\pi\colon R^2 - \{0, 0\} \to R^2 - \{0, 0\}$ given by

$$\pi(x, y) = (x^2 - y^2, 2xy), \quad (x, y) \in R^2,$$

is a two-sheeted covering map.

3. Let S be the helicoid generated by the normals to the helix $(\cos t, \sin t, bt)$. Denote by L the z axis and let $\pi\colon S - L \to R^2 - \{0, 0\}$ be the projection $\pi(x, y, z) = (x, y)$. Show that π is a covering map.

4. Those who are familiar with functions of a complex variable will have noticed that the map π in Exercise 2 is nothing but the map $\pi(z) = z^2$ from $\mathbb{C} - \{0\}$ onto $\mathbb{C} - \{0\}$; here $\mathbb{C}$ is the complex plane and $z \in \mathbb{C}$. Generalize that by proving that the map $\pi\colon \mathbb{C} - \{0\} \to \mathbb{C} - \{0\}$ given by $\pi(z) = z^n$ is an n-sheeted covering map.

5. Let $B \subset R^3$ be an arcwise connected set. Show that the following two properties are equivalent (cf. Def. 3):

1. For any pair of points $p, q \in B$ and any pair of arcs $\alpha_0\colon [0, l] \to B$, $\alpha_1\colon [0, l] \to B$, there exists a homotopy in B joining α_0 to α_1.
2. For any $p \in B$ and any arc $\alpha\colon [0, l] \to B$ with $\alpha(0) = \alpha(l) = p$ (that is, α is a closed arc with initial and end point p) there exists a homotopy joining α to the constant arc $\alpha(s) = p$, $s \in [0, l]$.

6. Fix a point $p_0 \in R^2$ and define a family of maps $\varphi_t\colon R^2 \to R^2$, $t \in [0, 1]$, by $\varphi_t(p) = tp_0 + (1 - t)p$, $p \in R^2$. Notice that $\varphi_0(p) = p$, $\varphi_1(p) = p_0$. Thus, φ_t is a continuous family of maps which starts with the identity map and ends with the constant map p_0. Apply these considerations to prove that R^2 is simply connected.

7. a. Use stereographic projection and Exercise 6 to show that any closed arc on a sphere S^2 which omits at least one point of S^2 is homotopic to a constant arc.

b. Show that any closed arc on S^2 is homotopic to a closed arc in S^2 which omits at least one point.

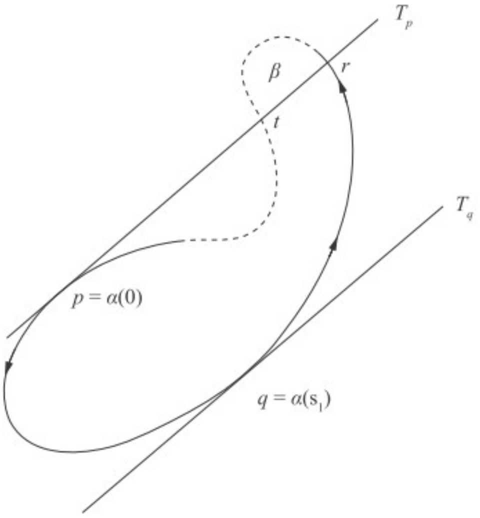

Figure 5-42

5-8. Surfaces of Zero Gaussian Curvature

We have already seen (Sec. 4-6) that the regular surfaces with identically zero Gaussian curvature are locally isometric to the plane. In this section, we shall look upon such surfaces from the point of view of their position in R^3 and prove the following global theorem.

THEOREM. *Let* $S \subset R^3$ *be a complete surface with zero Gaussian curvature. Then* S *is a cylinder or a plane.*

By definition, a *cylinder* is a regular surface S such that through each point $p \in S$ there passes a unique line $R(p) \subset S$ (the generator through p) which satisfies the condition that if $q \neq p$, then the lines $R(p)$ and $R(q)$ are parallel or equal.

It is a strange fact in the history of differential geometry that such a theorem was proved only somewhat late in its development. The first proof came as a corollary of a theorem of P. Hartman and L. Nirenberg ("On Spherical Images Whose Jacobians Do Not Change Signs," *Amer. J. Math.* 81 (1959), 901–920) dealing with a situation much more general than ours. Later, W. S. Massey ("Surfaces of Gaussian Curvature Zero in Euclidean Space," *Tohoku Math. J.* 14 (1962), 73–79) and J. J. Stoker ("Developable Surfaces in the Large," *Comm. Pure and Appl. Math.* 14 (1961), 627–635) obtained elementary and direct proofs of the theorem. The proof we present here is a modification of

Massey's proof. It should be remarked that Stoker's paper contains a slightly more general theorem.

(Added in 2016) Professor I. Sabitov informed me that this result was obtained by A.V. Pogorelov in 1956. It appeared under the title Extensions of the theorem of Gauss on spherical representation, in *Dokl. Akad. Nauk. S.S.S.R. (N.S.)* 111 (1956), 945–947. MR0087147.

We shall start with the study of some local properties of a surface of zero curvature.

Let $S \subset R^3$ be a regular surface with Gaussian curvature $K \equiv 0$. Since $K = k_1 k_2$, where k_1 and k_2 are the principal curvatures, the points of S are either parabolic or planar points. We denote by P the set of planar points and by $U = S - P$ the set of parabolic points of S.

P is closed in S. In fact, the points of P satisfy the condition that the mean curvature $H = \frac{1}{2}(k_1 + k_2)$ is zero. A point of accumulation of P has, by continuity of H, zero mean curvature; hence, it belongs to P. It follows that $U = S - P$ is open in S.

An instructive example of the relations between the sets P and U is given in the following example.

Example 1. Consider the open triangle *ABC* and add to each side a cylindrical surface, with generators parallel to the given side (see Fig. 5-43). It is possible to make this construction in such a way that the resulting surface is a regular surface. For instance, to ensure regularity along the open segment *BC*, it suffices that the section *FG* of the cylindrical band *BCDE* by a plane normal to *BC* is a curve of the form

$$\exp\left(-\frac{1}{x^2}\right).$$

Observe that the vertices A, B, C of the triangle and the edges *BE*, *CD*, etc., of the cylindrical bands do not belong to S.

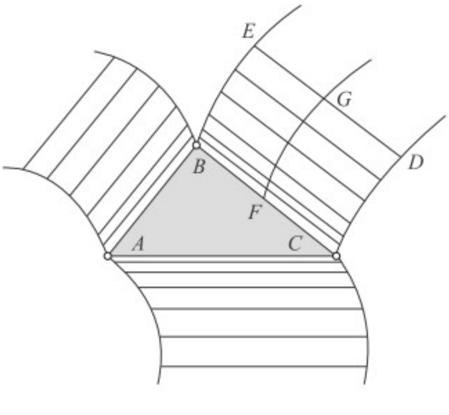

Figure 5-43

5- 6 26 T3

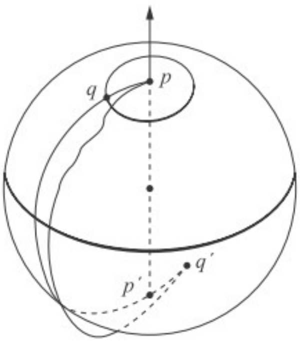

Figure 5-44

starting from a point p minimizes arc length, relative to "neighboring" curves of γ, only up to the "first" conjugate point of p relative to γ (more precise statements will be given later; see Theorems 1 and 2).

For simplicity, the surfaces in this section are assumed to be complete and the geodesics are parametrized by arc length.

We need some preliminary results.

The following lemma shows that the image by $\exp_p: T_p(S) \to S$ of a segment of line of $T_p(S)$ with origin at $O \in T_p(S)$ (geodesic starting from p) is minimal relative to the images by $\exp_p$ of curves of $T_p(S)$ which join the extremities of this segment.

More precisely, let

$$p \in S, \quad u \in T_p(S), \quad l = |u| \neq 0,$$

and let $\tilde{\gamma}: [0, l] \to T_p(S)$ be the line of $T_p(S)$ given by

$$\tilde{\gamma}(s) = sv, \quad s \in [0, l], \quad v = \frac{u}{|u|}.$$

Let $\tilde{\alpha}: [0, l] \to T_p(S)$ be a differentiable parametrized curve of $T_p(S)$, with $\tilde{\alpha}(0) = 0$, $\tilde{\alpha}(l) = u$, and $\tilde{\alpha}(s) \neq 0$ if $s \neq 0$. Furthermore, let (Fig. 5-45)

$$\alpha(s) = \exp_p \tilde{\alpha}(s) \quad \text{and} \quad \gamma(s) = \exp_p \tilde{\gamma}(s).$$

LEMMA 1. *With the above notation, we have*

1. $l(\alpha) \geq l(\gamma)$, *where* $l(\ )$ *denotes the arc length of the corresponding curve.*

In addition, if $\tilde{\alpha}(\mathrm{s})$ *is not a critical point of* $\exp_{\mathrm{p}}$, $\mathrm{s} \in [0, l)]$, *and if the traces of* α *and* γ *are distinct, then*

2. $l(\alpha) > l(\gamma)$.

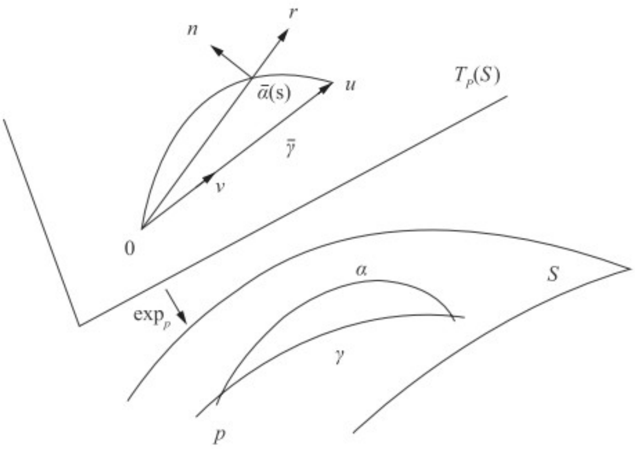

Figure 5-45

Proof. Let $\tilde{\alpha}(s)/|\tilde{\alpha}(s)| = r$, and let n be a unit vector of $T_p(S)$, with $\langle r, n\rangle = 0$. In the basis $\{r, n\}$ of $T_p(S)$ we can write (Fig. 5-45)

$$\tilde{\alpha}'(s) = ar + bn,$$

where

$$\begin{aligned} a &= \langle \tilde{\alpha}'(s), r\rangle, \\ b &= \langle \tilde{\alpha}'(s), n\rangle. \end{aligned}$$

By definition

$$\begin{aligned} \alpha'(s) &= (d\exp_p)_{\tilde{\alpha}(s)}(\tilde{\alpha}'(s)) \\ &= a(d\exp_p)_{\tilde{\alpha}(s)}(r) + b(d\exp_p)_{\tilde{\alpha}(s)}(n). \end{aligned}$$

Therefore, by using the Gauss lemma (cf. Sec. 5-5, Lemma 2) we obtain

$$\langle \alpha'(s), \alpha'(s)\rangle = a^2 + c^2,$$

where

$$c^2 = b^2|(d\exp_p)_{\tilde{\alpha}(s)}(n)|^2.$$

It follows that

$$\langle \alpha'(s), \alpha'(s)\rangle \geq a^2.$$

On the other hand,

$$\frac{d}{ds}\langle \tilde{\alpha}(s), \tilde{\alpha}(s)\rangle^{1/2} = \frac{\langle \tilde{\alpha}'(s), \tilde{\alpha}(s)\rangle}{\langle \tilde{\alpha}(s), \tilde{\alpha}(s)\rangle^{1/2}} = \langle \tilde{\alpha}'(s), r\rangle = a.$$

Therefore,

$$\begin{aligned} l(\alpha) &= \int_0^l \langle \alpha'(s), \alpha'(s)\rangle^{1/2}\, ds \geq \int_0^l a\, ds \\ &= \int_0^l \frac{d}{ds}\langle \tilde{\alpha}(s), \tilde{\alpha}(s)\rangle^{1/2}\, ds = |\tilde{\alpha}(l)| = l = l(\gamma), \end{aligned}$$

and this proves part 1.

To prove part 2, let us assume that $l(\alpha) = l(\gamma)$. Then

$$\int_0^l \langle \alpha'(s), \alpha'(s)\rangle^{1/2}\, ds = \int_0^l a\, ds,$$

and since

$$\langle \alpha'(s), \alpha'(s)\rangle^{1/2} \geq a,$$

the equality must hold in the last expression for every $s \in [0, l]$. Therefore,

$$c = |b||(d\exp_p)_{\tilde{\alpha}(s)}(n)| = 0.$$

Since $\tilde{\alpha}(s)$ is not a critical point of $\exp_p$, we conclude that $b \equiv 0$. It follows that the tangent lines to the curve $\tilde{\alpha}$ all pass through the origin O of $T_p(s)$. Thus, $\tilde{\alpha}$ is a line of $T_p(S)$ which passes through O. Since $\tilde{\alpha}(l) = \tilde{\gamma}(l)$, the lines $\tilde{\alpha}$ and $\tilde{\gamma}$ coincide, thus contradicting the assumption that the traces of α and γ are distinct. From this contradiction it follows that $l(\alpha) > l(\gamma)$, which proves part 2 and ends the proof of the lemma. **Q.E.D.**

We are now in a position to prove that if a geodesic arc contains no conjugate points, it yields a local minimum for the arc length. More precisely, we have

THEOREM 1 (Jacobi). *Let* $\gamma\colon [0, l] \to \mathrm{S}$, $\gamma(0) = \mathrm{p}$, *be a geodesic without conjugate points; that is,* $exp_{\mathrm{p}}\colon \mathrm{T_p(S)} \to \mathrm{S}$ *is regular at the points of the line* $\tilde{\gamma}(\mathrm{s}) = \mathrm{s}\gamma'(0)$ *of* $\mathrm{T_p(S)}$, $\mathrm{s} \in [0, l]$. *Let* $\mathrm{h}\colon [0, l] \times (-\epsilon, \epsilon) \to \mathrm{S}$ *be a proper variation of* γ. *Then*

1. *There exists a* $\delta > 0$, $\delta \leq \epsilon$, *such that if* $\mathrm{t} \in (-\delta, \delta)$,

$$\mathrm{L(t)} \geq \mathrm{L(0)},$$

where $\mathrm{L(t)}$ *is the length of the curve* $\mathrm{h_t}\colon [0, l] \to \mathrm{S}$ *that is given by* $\mathrm{h_t(s)} = \mathrm{h(s, t)}$.

2. *If, in addition, the trace of* $\mathrm{h_t}$, *is distinct from the trace of* γ, $\mathrm{L(t)} > \mathrm{L(0)}$.

Proof. The proof consists essentially of showing that it is possible, for every $t \in (-\delta, \delta)$, to lift the curve h_t into a curve $\tilde{h}_t$ of $T_p(S)$ such that $\tilde{h}_t(0) = 0$, $\tilde{h}_t(l) = \tilde{\gamma}(l)$ and then to apply Lemma 1.

Show that the curvature of this metric is given by

$$\frac{\partial^2(\sqrt{G})}{\partial x^2} + K(x, y)\sqrt{G} = 0. \tag{$*$}$$

b. Conversely, given a function $K(x, y)$ on R^2, regard y as a parameter and let $\sqrt{G}$ be the solution of $(*)$ with the initial conditions

$$\sqrt{G}(x_0, y) = 1, \quad \frac{\partial\sqrt{G}}{\partial x}(x_0, y) = 0.$$

Prove that G is positive in a neighborhood of (x_0, y) and thus defines a metric in this neighborhood. This shows that *every differentiable function is locally the curvature of some (abstract) metric.*

***c.** Assume that $K(x, y) \leq 0$ for all $(x, y) \in R^2$. Show that the solution of part b satisfies

$$\sqrt{G(x, y)} \geq \sqrt{G(x_0, y)} = 1 \quad \text{for all } x.$$

Thus, $G(x, y)$ defines a metric on all of R^2. Prove also that this metric is complete. This shows that *any nonpositive differentiable function on* R^2 *is the curvature of some complete metric on* R^2. If we do not insist on the metric being complete, the result is true for any differentiable function K on R^2. Compare J. Kazdan and F. Warner, "Curvature Functions for Open 2-Manifolds," *Ann. of Math.* 99 (1974), 203–219, where it is also proved that the condition on K given in Exercise 2 of Sec. 5-4 is necessary and sufficient for the metric to be complete.

5-11. Hilbert's Theorem

Hilbert's theorem can be stated as follows.

THEOREM. *A complete geometric surface* S *with constant negative curvature cannot be isometrically immersed in* R^3.

Remark 1. Hilbert's theorem was first treated in D. Hilbert, "Über Flächen von konstanter Gausscher Krümung," *Trans. Amer. Math. Soc.* 2 (1901), 87–99. A different proof was given shortly after by E. Holmgren, "Sur les surfaces à courbure constante negative," *C. R. Acad. Sci. Paris* 134 (1902), 740–743. The proof we shall present here follows Hilbert's original ideas. The local part is essentially the same as in Hilbert's paper; the global part, however, is substantially different. We want to thank J. A. Scheinkman for helping us to work out this proof.

We shall start with some observations. By multiplying the inner product by a constant factor, we may assume that the curvature $K \equiv -1$. Moreover, since $\exp_p : T_p(S) \to S$ is a local diffeomorphism (corollary of the theorem of Sec. 5-5), it induces an inner product in $T_p(S)$. Denote by S' the geometric surface $T_p(S)$ with this inner product. If $\psi: S \to R^3$ is an isometric immersion, the same holds for $\varphi = \psi \circ \exp_p : S' \to R^3$. Thus, we are reduced to proving that there exists no isometric immersion $\varphi: S' - R^3$ of a plane S' with an inner product such that $K \equiv -1$.

LEMMA 1. *The area of* S′ *is infinite.*

Proof. We shall prove that S' is (globally) isometric to the hyperbolic plane H. Since the area of the latter is (cf. Example 3, Sec. 5-10)

$$\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} e^u\, du\, dv = \infty,$$

this will prove the lemma.

Let $p \in H$, $p' \in S'$, and choose a linear isometry ψ: $T_p(H) \to T_{p'}(S')$ between their tangent spaces. Define a map φ: $H \to S'$ by $\varphi = \exp_p \circ \psi \circ \exp_p^{-1}$. Since each point of H is joined to p by a unique minimal geodesic, φ is well defined.

We now use polar coordinates (p, θ) and (p', θ') around p and p', respectively, requiring that φ maps the axis $\theta = 0$ into the axis $\theta' = 0$. By the results of Sec. 4-6, φ preserves the first fundamental form; hence, it is locally an isometry. By using the remark made after Hadamard's theorem, we conclude that φ is a covering map. Since S' is simply connected, φ is a homeomorphism, and hence a (global) isometry. **Q.E.D.**

For the rest of this section we shall assume that there exists an isometric immersion φ: $S' \to R^3$, where S' is a geometric surface homeomorphic to a plane and with $K \equiv -1$.

To avoid the difficulties associated with possible self-intersections of $\varphi(S')$, we shall work with S' and use the immersion φ to induce on S' the local extrinsic geometry of $\varphi(S') \subset R^3$. More precisely, since φ is an immersion, for each $p \in S'$ there exists a neighborhood $V' \subset S'$ of p such that the restriction $\varphi|V' = \tilde{\varphi}$ is a diffeomorphism. At each $\tilde{\varphi}(q) \in \tilde{\varphi}(V')$, there exist, for instance, two asymptotic directions. Through $\tilde{\varphi}$, these directions induce two directions at $q \in S'$, which will be called *the asymptotic directions on* S' at q. In this way, it makes sense to talk about asymptotic curves on S', and the *same procedure can be applied to any other local entity of* $\varphi(S')$.

We now recall that the coordinate curves of a parametrization constitute a *Tchebyshef net* if the opposite sides of any quadrilateral formed by them have equal length (cf. Exercise 7, Sec. 2-5). If this is the case, it is possible to reparametrize the coordinate neighborhood in such a way that $E = 1$,

$F = \cos\theta$, $G = 1$, where θ is the angle formed by the coordinate curves, (Sec. 2-5, Exercise 8). Furthermore, in this situation, $K = -(\theta_{uv}/\sin\theta)$ (Sec. 4-3, Exercise 5).

LEMMA 2. *For each* $p \in S'$ *there is a parametrization* $\mathbf{x}: U \subset R^2 \to S'$, $p \in \mathbf{x}(U)$*, such that the coordinate curves of* $\mathbf{x}$ *are the asymptotic curves of* $\mathbf{x}(U) = V'$ *and form a Tchebyshef net* (we shall express this by saying that the asymptotic curves of V' form a Tchebyshef net).

Proof. Since $K < 0$, a neighborhood $V' \subset S'$ of p can be parametrized by $\mathbf{x}(u, v)$ in such a way that the coordinate curves of $\mathbf{x}$ are the asymptotic curves of V'. Thus, if e, f, and g are the coefficients of the second fundamental form of S' in this parametrization, we have $e = g = 0$. Notice that we are using the above convention of referring to the second fundamental form of S' rather than the second fundamental form of $\varphi(S') \subset R^3$.

Now $\varphi(V') \subset R^3$, we have

$$N_u \wedge N_v = K(\mathbf{x}_u \wedge \mathbf{x}_v);$$

hence, setting $D = \sqrt{EG - F^2}$,

$$(N \wedge N_v)_u - (N \wedge N_u)_v = 2(N_u \wedge N_v) = 2KDN.$$

Furthermore,

$$\begin{aligned} N \wedge N_u &= \frac{1}{D}\{(\mathbf{x}_u \wedge \mathbf{x}_v) \wedge N_u\} = \frac{1}{D}\{\langle \mathbf{x}_u, N_u\rangle \mathbf{x}_v - \langle \mathbf{x}_v, N_u\rangle \mathbf{x}_u\} \\ &= \frac{1}{D}(f\mathbf{x}_u - e\mathbf{x}_v), \end{aligned}$$

and, similarly,

$$N \wedge N_v = \frac{1}{D}(g\mathbf{x}_u - f\mathbf{x}_v).$$

Since $K = -1 = -(f^2/D^2)$ and $e = g = 0$, we obtain

$$N \wedge N_u = \pm\mathbf{x}_u, \quad N \wedge N_v = \pm\mathbf{x}_v;$$

hence

$$2KDN = -2DN = \pm\mathbf{x}_{uv} \pm \mathbf{x}_{vu} = \pm 2\mathbf{x}_{uv}.$$

It follows that $\mathbf{x}_{uv}$ is parallel to N; hence, $E_v = 2\langle \mathbf{x}_{uv}, \mathbf{x}_u\rangle = 0$ and $G_u = 2\langle \mathbf{x}_{uv}, \mathbf{x}_v\rangle = 0$. But $E_v = G_u = 0$ implies (Sec. 2-5, Exercise 7) that the coordinate curves form a Tchebysbef net. **Q.E.D.**

LEMMA 3. *Let* $V' \subset S'$ *be a coordinate neighborhood of* S' *such that the coordinate curves are the asymptotic curves in* V'*. Then the area* A *of any quadrilateral formed by the coordinate curves is smaller than* 2π.

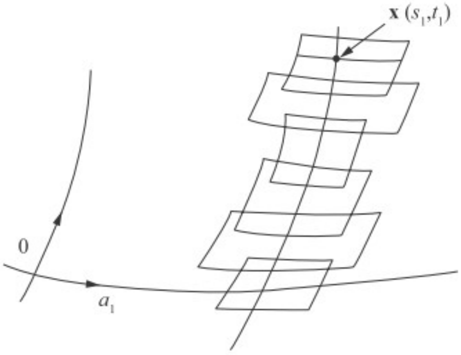

Figure 5-56

LEMMA 6. **x** *is surjective.*

Proof. Let $Q = \mathbf{x}(R^2)$. Since **x** is a local diffeomorphism, Q is open in S'. We also remark that if $p' = \mathbf{x}(s_0, t_0)$, then the two asymptotic curves which pass through p' are entirely contained in Q.

Let us assume that $Q \neq S'$. Since S' is connected, the boundary Bd $Q \neq \phi$. Let $p \in$ Bd Q. Since Q is open in S', $p \notin Q$. Now consider a rectangular neighborhood R of p in which the asymptotic curves form a Tchebyshef net (Fig. 5-57). Let $q \in Q \cap R$. Then one of the asymptotic curves through q intersects one of the asymptotic curves through p. By the above remark, this is a contradiction. **Q.E.D.**

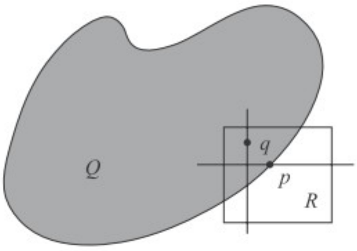

Figure 5-57

We now claim that **x** is a global diffeomorphism. Since **x** is a surjective local diffeomorphism, it suffices to show x has the property of lifting arcs and apply Prop. 6 of Sec. 5-6 (Covering Spaces...) to conclude that **x** is a covering map. Since R^2 is simply connected, this will prove our claim.

To show that **x** has the property of lifting arcs we use a Proposition that is presented here without proof (For a proof, see Elon Lima, Fundamental Groups and Covering Spaces, A K Peters, Natick, Massachusetts, see p. 144): ... *Let* **x**: $\mathrm{R}^2 \to \mathrm{S}'$ *be a surjective local diffeomorphism. Assume that* **x** *is a closed map (i.e., the image of a closed set is closed). Then* **x** *has the property of lifting arcs*. That **x** is closed follows from the way it is defined.

This completes the proof of our claim.

The proof of Hilbert's theorem now follows easily.

Proof of the Theorem. Assume the existence of an isometric immersion $\psi\colon S \to R^3$, where S is a complete surface with $K \equiv -1$. Let $p \in S$ and denote by S' the tangent plane $T_p(S)$ endowed with the metric induced by $\exp_p\colon T_p(S) \to S$. Then $\varphi = \psi \circ \exp_p\colon S' \to R^3$ is an isometric immersion and Lemmas 5 and 6 plus the text after them show the existence of a parametrization $\mathbf{x}\colon R^2 \to S'$ of the entire S' such that the coordinate curves of $\mathbf{x}$ are the asymptotic curves of S' (Lemma 4). Thus, we can cover S' by a union of "coordinate quadrilaterals" Q_n, with $Q_n \subset Q_{n+1}$. By Lemma 3, the area of each Q_n is smaller than 2π. On the other hand, by Lemma 1, the area of S' is unbounded. This is a contradiction and concludes the proof. **Q.E.D.**

Remark 2. Hilbert's theorem was generalized by N. V. Efimov, "Appearance of Singularities on Surfaces of Negative Curvature," *Math. Sb.* 106 (1954). A.M.S. Translations. Series 2, Vol. 66, 1968, 154–190, who proved the following conjecture of Cohn-Vossen: *Let* S *be a complete surface with curvature* K *satisfying* $K \le \delta < 0$. *Then there exists no isometric immersion of* S *into* R^3. Efimov's proof is very long, and a shorter proof would be desirable.

An excellent exposition of Efimov's proof can be found in a paper by T. Klotz Milnor, "Efimov's Theorem About Complete Immersed Surfaces of Negative Curvature," *Advances in Mathematics* 8 (1972), 474–543. This paper also contains another proof of Hilbert's theorem which holds for surfaces of class C^2.

For further details on immersion of the hyperbolic plane see M. L. Cromov and V. A. Rokblin, "Embeddings and Immersions in Riemannian Geometry," *Russian Math. Sureys* (1970), 1–57, especially p. 15.

EXERCISES

1. (*Stoke's Remark.*) Let S be a complete geometric surface. Assume that the Gaussian curvature K satisfies $K \le \delta < 0$. Show that there is no isometric immersion $\varphi\colon S \to R^3$ such that the absolute value of the mean curvature H is bounded. This proves Efimov's theorem quoted in Remark 2 with the additional condition on the mean curvature. The following outline may be useful:

a. Assume such a φ exists and consider the Gauss map $N\colon \varphi(S) \subset R^3 \to S^2$, where S^2 is the unit sphere. Since $K \neq 0$ everywhere, N induces a new metric (,) on S by requiring that $N \circ \varphi\colon S \to S^2$ be a local isometry. Choose coordinates on S so that the images by φ of the coordinate curves are lines of curvature of $\varphi(S)$. Show that the coefficients of the new metric in this coordinate system are

$$g_{11} = (k_1)^2 E, \quad g_{12} = 0, \quad g_{22} = (k_2)^2 G,$$

One of the surprising results about linking is Gauss's formula for the linking number between two curves. Though linking and the linking number are obviously global properties of the curves, Gauss's formula calculates the linking number in terms of the parametrizations of the curves, thereby connecting the global property to local properties.

Theorem 4.3.4 (Gauss's Linking Formula). *Let C_1 and C_2 be two closed, regular, space curves parametrized by $\vec{\alpha} : I \to \mathbb{R}^3$ and $\vec{\beta} : J \to \mathbb{R}^3$, respectively. The linking number between C_1 and C_2 is*

$$\operatorname{link}(C_1, C_2) = \frac{1}{4\pi} \int_I \int_J \frac{\det(\vec{\alpha}(u) - \vec{\beta}(v), \vec{\alpha}'(u), \vec{\beta}'(v))}{\|\vec{\alpha}(u) - \vec{\beta}(v)\|^3}\, du\, dv. \quad (4.8)$$

Though we cannot give a proof for this formula at this time, we briefly sketch a few of the concepts and techniques that go into it.

In Section 2.2, we introduced the notion of degree for a continuous map between circles, $f : \mathbb{S}^1 \to \mathbb{S}^1$. Intuitively speaking, the degree of f counts how many times f covers its codomain and with what orientation. The degree of f takes into account when f might double back. For example, if $q \in \mathbb{S}^1$ has six preimages from f and, for four of the preimages, f pass through q with the same orientation as on the domain and, for the other two preimages, f passes through q in an opposite orientation, then the degree of f is $4 - 2 = 2$.

Similarly, in the field of algebraic topology, a topic that is outside the scope of this book, one can define the degree of a map between spheres $f : \mathbb{S}^2 \to \mathbb{S}^2$ as how often f covers $\mathbb{S}^2$. Again, one should note the difficulty inherent in making this definition precise since one must take into account a form of orientation and doubling back, i.e., whether f folds back over itself over some region of the codomain. In the same way, one can define the degree of a continuous map $F : S \to \mathbb{S}^2$, where S is a regular surface without boundary. (We give the definition for a regular surface in Chapter 5.) The conditions that S is regular and has no boundary guarantees that F generically covers $\mathbb{S}^2$ by the same amount at all its points, so long as we take into account orientation and assign a negative covering value to F when F covers $\mathbb{S}^2$ negatively.

As discussed in Definition 2.2.5 and in the following, it is more appropriate to view the parametrization of a simple closed curve C

5- N 2 7T3

6.2 The Gauss Map

In Section 2.2, given any closed, simple, regular curve $\gamma : I \to \mathbb{R}^2$ in the plane, we defined the tangential indicatrix to be the curve given by $\vec{T} : I \to \mathbb{R}^2$, the unit tangent vector of $\gamma(t)$. The image of $\vec{T}$ lies on the unit circle, and though $\vec{T}$ is a closed curve, it need not be regular as its locus may stop and double back. Regardless of the parametrization, the tangential indicatrix is well defined up to a change in sign.

On any regular surface S in $\mathbb{R}^3$, the tangent plane T_pS at a point $p \in S$ is a two-dimensional subspace of $\mathbb{R}^2$, and hence the vectors that are normal to S at p form a one-dimensional subspace. Thus, there exist exactly two possible choices for a unit normal vector. Proposition 5.5.4 implies that if the surface is orientable, we can specify its orientation by a continuous function $n : S \to \mathbb{S}^2$, where $\mathbb{S}^2$ means the unit sphere in $\mathbb{R}^3$.

Definition 6.2.1. Let S be an oriented regular surface in $\mathbb{R}^3$ with an orientation $n : S \to \mathbb{S}^2$. In the classical theory of surfaces, the function n is also called the *Gauss map*.

It is important to remain aware of the distinction between the functions n and $\vec{N}$. Let S be an oriented surface with orientation $n : S \to \mathbb{S}^2$. Suppose that $\vec{X} : U \to \mathbb{R}^3$, where U is an open subset of $\mathbb{R}^2$, parametrizes a neighborhood of S, then the function $\vec{N} : U \to \mathbb{S}^2$ is defined in reference to $\vec{X}$ by Equation (5.9). The functions n and $\vec{N}$ are related by the fact that if $\vec{X}$ is a positively oriented parametrization, then

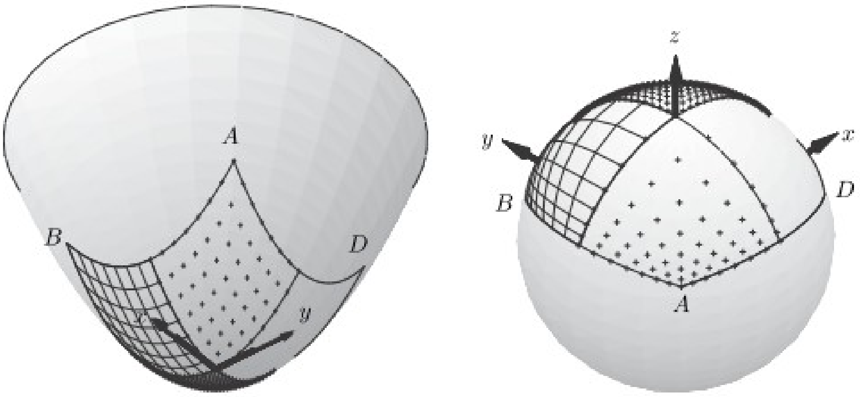
$$\vec{N} = n \circ \vec{X}.$$

Example 6.2.2. Consider as an example a sphere S in $\mathbb{R}^3$ equipped with the orientation n, with the unit vectors normal to S pointing away from the center $\vec{c}$ of the sphere. The sphere can be given as the solution to the equation

$$\|\vec{x} - \vec{c}\|^2 = R^2. \tag{6.10}$$

Recall that $\|\vec{v}\|^2 = \vec{v} \cdot \vec{v}$. If $\vec{x}(t)$ is any curve on the sphere, then by differentiating the relationship in Equation (6.10), one obtains

$$\vec{x}'(t) \cdot (\vec{x}(t) - \vec{c}) = 0.$$



(a) Elliptic paraboloid (b) Unit sphere

Figure 6.4. Gauss map on the elliptic paraboloid.

The tangent plane to the sphere S at a point $\vec{p}$ consists of all possible vectors $\vec{x}'(t_0)$, where $\vec{x}(t)$ is a curve on S, with $\vec{x}(t_0) = \vec{p}$. Therefore, at any point $\vec{p}$ on the sphere, there are two options for unit normal vectors:

$$\frac{\vec{p}-\vec{c}}{\|\vec{p}-\vec{c}\|} \quad \text{or} \quad -\frac{\vec{p}-\vec{c}}{\|\vec{p}-\vec{c}\|}$$

However, it is the former that provides the outward-pointing orientation n. Thus the Gauss map for the sphere of radius R and center $\vec{c}$ is explicitly

$$n(\vec{p}) = \frac{\vec{p}-\vec{c}}{R}.$$

Furthermore, if S is itself the unit sphere centered at the origin, then the Gauss map is the identity function.

Example 6.2.3. Consider the elliptic paraboloid S defined by the equation $z = x^2 + y^2$. This is an orientable surface, and suppose it is oriented with the unit normal always pointing in a positive z-direction. (Figure 6.4 shows this is possible.) Using the function $F(x, y, z) = z - x^2 - y^2$, the elliptic paraboloid is given by the equation $F(x, y, z) = 0$. By Proposition 5.2.13, for all $(x, y, z) \in S$, the gradient $\vec{\nabla}F(x,y,z)$ is a normal vector, so (since the z-direction is positive) the Gauss map is

$$n(x,y,z) = \frac{(-2x,-2y,1)}{\sqrt{4x^2+4y^2+1}}.$$

Figure 6.4 shows how the Gauss map acts on the patch

$$\{(x,y,z) \in S \mid -1 \le x \le 1 \text{ and } -1 \le y \le 1\}.$$

It is not hard to show that the image of the Gauss map on the unit sphere is the upper hemisphere. Indeed, using cylindrical coordinates, the Gauss map is

$$n(r,\theta,z) = \frac{(-2r\cos\theta,-2r\sin\theta,1)}{\sqrt{4r^2+1}}.$$

The function $f(r) = 1/\sqrt{4r^2+1}$ is a decreasing bijection from $[0,+\infty)$ to $(0,1]$. Thus, for any $z_0 \in (0,1]$, there exists a unique $r_0 \in [0,+\infty)$ with $f(r_0) = z_0$. Then, with $\theta \in [0,2\pi]$, the image of $n(r_0,\theta,z_0)$ is a circle on the unit sphere at height z_0. Thus, the image of n is

$$n(S) = \{(x,y,z) \in \mathbb{S}^2 \mid z > 0\}.$$

Example 6.2.4. In contrast to Example 6.2.3, consider the hyperbolic paraboloid given by the parametrization $\vec{X} : \mathbb{R}^2 \to \mathbb{R}^3$, with

$$\vec{X}(u,v) = (u,v,u^2-v^2).$$

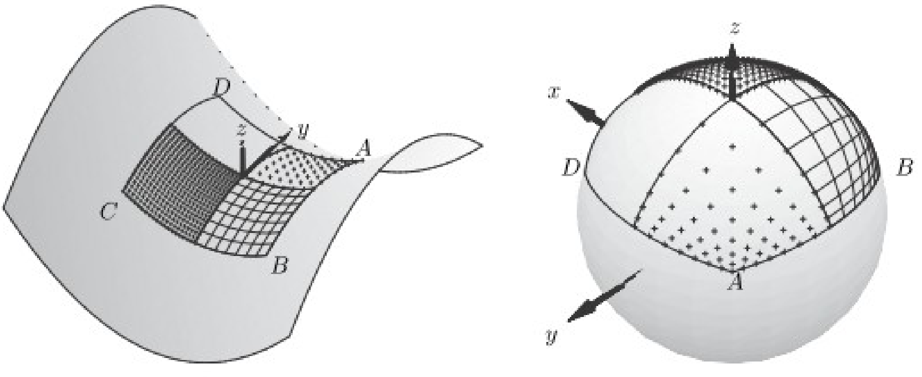
We calculate

$$\vec{X}_u = (1,0,2u) \qquad \text{and} \qquad \vec{X}_v = (0,1,-2v),$$

and thus,

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\|\vec{X}_u \times \vec{X}_v\|} = \frac{(-2u,2v,1)}{\sqrt{4u^2+4v^2+1}}.$$

Like Figure 6.4, Figure 6.5 shows the Gauss map for a "square" on the hyperbolic paraboloid. These two examples manifest a central behavior of the Gauss map. On the elliptic paraboloid, the Gauss



(a) Hyperbolic paraboloid (b) Unit sphere

Figure 6.5. Gauss map on the hyperbolic paraboloid.

map preserves the orientation of the square in the sense that if one travels along the boundary in a clockwise sense on the surface, one also travels along the boundary of the image of the square mapped by n in a clockwise sense. On the other hand, with the hyperbolic paraboloid, the Gauss map reverses the orientation of the square.

Proposition 6.2.5. *Let S be a regular surface in $\mathbb{R}^3$, and let $\vec{X} : U \to \mathbb{R}^3$ be a parametrization of a coordinate patch $V = \vec{X}(U)$, where U is an open set in $\mathbb{R}^2$. Define the vector function $\vec{N} : U \to \mathbb{R}^3$ by*

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\|\vec{X}_u \times \vec{X}_v\|}.$$

If $\vec{X}$ is of class C^r, then $\vec{N}$ is of class C^{r-1}.

Proof: By Problem 3.1.10, we deduce that if $\vec{F} : U \to \mathbb{R}^3$, $\vec{G} : U \to \mathbb{R}^3$, and $h : U \to \mathbb{R}$ are of class C^1, then the three functions $\vec{F} \cdot \vec{G} : U \to \mathbb{R}$, $\vec{F} \times \vec{G} : U \to \mathbb{R}^3$, and $h\vec{F} : U \to \mathbb{R}^3$ are also of class C^1, and their partial derivatives follow appropriate product rules. By definition,

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\sqrt{(\vec{X}_u \times \vec{X}_v) \cdot (\vec{X}_u \times \vec{X}_v)}}.$$

One can see that any partial derivative of any order of $\vec{N}$ will involve the partial derivative of a combination of the above three types of products and the derivative of an expression of the form

$$f(u,v) = \left((\vec{X}_u \times \vec{X}_v) \cdot (\vec{X}_u \times \vec{X}_v)\right)^{-k/2},$$

where k is an odd positive integer. Since S is regular, $\|\vec{X}_u \times \vec{X}_v\|$ is never 0, so a particular higher derivative of $\vec{N}$ will exist if that higher derivative exists for $\vec{X}_u$ and for $\vec{X}_v$. The proposition follows. $\square$

One would be correct to think that the different behaviors in Figures 6.4 and 6.5 can be illustrated and quantified by a function between tangent spaces to S and $\mathbb{S}^2$, respectively. This perspective is encapsulated in the notion of the differential of functions between regular surfaces. We develop the more general theory of differentials of functions between manifolds in Chapter 3 of [22]. However, the differential of the Gauss map, though only a particular case of the differentials of functions between surfaces, serves a central role in the rest of this chapter.

Let S be a regular oriented surface with orientation n, and let $\vec{X} : U \to \mathbb{R}^3$ be a regular positively oriented parametrization of a coordinate patch $\vec{X}(U)$ of S. Suppose also that S is of class C^2, which, according to Proposition 6.2.5, implies that $\vec{N}$ is of class C^1. Since $\vec{N} \cdot \vec{N} = 1$ for all $(u,v) \in U$, we have

$$\vec{N} \cdot \vec{N}_u = 0 \qquad \text{and} \qquad \vec{N} \cdot \vec{N}_v = 0 \tag{6.11}$$

for all $(u,v) \in U$. Therefore, both derivatives $\vec{N}_u$ and $\vec{N}_v$ are vector functions such that $\vec{N}_u(q)$ and $\vec{N}_v(q)$ are in T_pS when $\vec{X}(q) = p$.

The vector function $\vec{N} : U \to \mathbb{R}^3$ is itself a parametrized surface, with its image lying in the unit sphere, though not necessarily giving a regular parametrization of $\mathbb{S}^2$. The simple fact in Equation (6.11) indicates that if $\vec{N}$ admits a tangent plane at $q \in U$, then

$$T_pS = T_{\vec{N}(q)}(\mathbb{S}^2) \tag{6.12}$$

as subspaces of $\mathbb{R}^3$. In other words, the sets of vectors $\{\vec{X}_u, \vec{X}_v\}$ and $\{\vec{N}_u, \vec{N}_v\}$ span the same subspace T_pS.

The differential of the Gauss map at a point $p \in S$ is a linear transformation $dn_p : T_pS \to T_{n(p)}(\mathbb{S}^2)$, but by virtue of Equation (6.12), one identifies it as a linear transformation $dn_p : T_pS \to T_pS$. For all $\vec{v} \in T_pS$, one defines $dn_p(\vec{v}) = \vec{w}$ if there exists a curve $\vec{\alpha} : I \to U$ such that

$$\begin{cases} \vec{\alpha}(0) = q, \text{ with } \vec{X}(q) = p, \\ \dfrac{d}{dt}\left(\vec{X} \circ \vec{\alpha}\right)(t)\big|_{t=0} = \vec{v}, \text{ and} \\ \dfrac{d}{dt}\left(\vec{N} \circ \vec{\alpha}\right)(t)\big|_{t=0} = \vec{w}. \end{cases} \tag{6.13}$$

In other words, by writing $\vec{X}(t) = \vec{X} \circ \vec{\alpha}(t)$ and $\vec{N}(t) = \vec{N} \circ \vec{\alpha}(t)$, the differential of the Gauss map satisfies $dn_p(\vec{X}'(0)) = \vec{N}'(0)$.

Using coordinate lines $\vec{X}(t, v_0)$ or $\vec{X}(u_0, t)$ for the curve $\vec{\alpha}(t)$ in the above definition, it is easy to see that

$$\begin{aligned} dn_p(\vec{X}_u) &= \vec{N}_u, \\ dn_p(\vec{X}_v) &= \vec{N}_v. \end{aligned} \tag{6.14}$$

Though the Gauss map $n : S \to \mathbb{S}^2$ is independent of any coordinate systems on S, the differential dn_p requires reference to a regular positively oriented parametrization of a neighborhood of p. However, though different parametrizations of a neighborhood of p induce different coordinate bases on T_pS, the definition in Equation 6.13 remains unchanged and consequently, as a linear transformation of T_pS to itself, is independent of the parametrization.

Problems

6.2.1. Describe the region of the unit sphere covered by the image of the Gauss map for the following surfaces:

(a) The hyperbolic paraboloid given by $z = x^2 - y^2$.

(b) The hyperboloid of one sheet given by $x^2 + y^2 - z^2 = 1$.

(c) The cone with opening angle α given by $z^2 \tan^2 \alpha = x^2 + y^2$.

(d) The right circular cylinder $x^2 + y^2 = R^2$, with R a constant.

6.2.2. What regular surface S has a single point on $\mathbb{S}^2$ as the image of the Gauss map?

5- T<2 73

6.5 Gaussian and Mean Curvature

We now arrive at two fundamental geometric invariants that encapsulate a considerable amount of useful information about the local shape of a surface. Again, in this section, we must assume that S is a regular surface of class C^2.

Definition 6.5.1. Let κ_1 and κ_2 be the principal curvatures of a regular surface S at a point p. Define

1. the *Gaussian curvature* of S at p as the product $K = \kappa_1\kappa_2$;
2. the *mean curvature* of S at p as the average $H = \frac{\kappa_1+\kappa_2}{2}$ of the principal curvatures.

By Problem 6.3.6, the matrix for the Gauss map in terms of any particular coordinate system on a neighborhood of p on S is conjugate to the corresponding matrix for a different coordinate system via the change of basis matrix $\left(\frac{\partial x_i}{\partial \bar{x}_j}\right)$. Therefore, since $\det(BAB^{-1}) = \det(A)$ and $\mathrm{Tr}(BAB^{-1}) = \mathrm{Tr}(A)$, which is a standard result in linear algebra, the eigenvalues of the Gauss map, the principal curvatures, the Gaussian curvature, and the mean curvature are invariant under coordinate changes. Furthermore, since $\det(-A) = \det(A)$ when A is a square matrix with an even number of rows, then

$$\begin{aligned} K &= \kappa_1\kappa_2 = \det(a_i^j) = \det(dn_p), \\ H &= \frac{\kappa_1+\kappa_2}{2} = -\frac{1}{2}\,\mathrm{Tr}(a_i^j) = -\frac{1}{2}\,\mathrm{Tr}(dn_p). \end{aligned}$$

Consequently, as claimed above, the Gaussian curvature and the mean curvature of S at p are geometric invariants. This means that they do not depend on the orientation or position of S in space, and they do not depend on any particular coordinate system on S in a neighborhood of the point p.

In order to calculate the mean curvature $H(u, v)$, one has no choice but to calculate the matrix of the differential of the Gauss map $(a_j^i) = [dn_p]$. However, from a computational perspective, Equation (6.26) leads to a much simpler formula for the Gaussian curvature function $K(u, v)$. Recall that $\det(AB) = \det(A)\det(B)$ for all square matrices of the same size and also that $\det(A^{-1}) = 1/\det(A)$. Then Equation (6.26) implies that

$$K = \frac{\det(L_{ij})}{\det(g_{ij})} = \frac{L_{11}L_{22} - L_{12}^2}{g_{11}g_{22} - g_{12}^2}. \tag{6.37}$$

This equation lends itself readily to calculations since one does not need to fully compute the matrix of the Gauss map, let alone find its eigenvalues. However, we can also obtain an alternate characterization of the Gaussian curvature.

Proposition 6.5.2. *Let S be a regular surface of class C^2, and let V be a neighborhood parametrized by $\vec{X} : U \subset \mathbb{R}^2 \to \mathbb{R}^3$. Define the unit normal vector $\vec{N}$ as*

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\|\vec{X}_u \times \vec{X}_v\|}.$$

Then over the domain U, the Gaussian curvature is the unique function $K(u,v)$ satisfying

$$\vec{N}_u \times \vec{N}_v = K(u,v)\vec{X}_u \times \vec{X}_v$$

Proof: From the definition of the (a^i_j) functions in Equation (6.22), we have

$$\vec{N}_u \times \vec{N}_v = (a^1_1\vec{X}_u + a^2_1\vec{X}_v) \times (a^1_2\vec{X}_u + a^2_2\vec{X}_v).$$

It is then easy to see that

$$\vec{N}_u \times \vec{N}_v = \det(a^i_j)\vec{X}_u \times \vec{X}_v.$$

The result follows since $K = \det(a^i_j)$. □

Example 6.5.3 (Spheres). Consider the sphere parametrized by the vector function

$$\vec{X}(u,v) = (R\cos u \sin v, R\sin u \sin v, R\cos v),$$

with $(u,v) \in (0, 2\pi) \times (0, \pi)$. Example 6.1.5 and Example 6.3.3 gave us

$$(g_{ij}) = \begin{pmatrix} R^2\sin^2 v & 0 \\ 0 & R^2 \end{pmatrix} \qquad \text{and} \qquad (L_{ij}) = \begin{pmatrix} -R\sin^2 v & 0 \\ 0 & -R \end{pmatrix}.$$

Using Equation (6.37), it is then easy to see that the Gaussian curvature function on the sphere is

$$K(u,v) = \frac{R^2 \sin^2 v}{R^4 \sin^2 v} = \frac{1}{R^2},$$

which is a constant function. (Note that we assumed that $v \neq 0$, π, which correspond to the north and south poles of the parametrization. However, another parametrization that includes the north and south poles would show that at these points as well we have $K = 1/R^2$.)

The matrix of the Gauss map is then

$$[dn_p] = -Lg^{-1} = \begin{pmatrix} -\frac{1}{R} & 0 \\ 0 & -\frac{1}{R} \end{pmatrix},$$

from which one immediately deduces that the principal curvatures are $\kappa_1(u,v) = \kappa_2(u,v) = \frac{1}{R}$. This shows that all points on the sphere are umbilical points. In addition, the mean curvature is also a constant function $H(u,v) = \frac{1}{R}$.

Example 6.5.4 (Function Graphs). Consider the graph of a function $f : U \subset \mathbb{R}^2 \to \mathbb{R}$. The graph can be parametrized by $\vec{X} : U \to \mathbb{R}^3$, with

$$\vec{X}(u,v) = (u, v, f(u,v)).$$

Problem 6.3.7 asks the reader to calculate the matrix (L_{ij}). It is not hard to show that

$$(g_{ij}) = \begin{pmatrix} 1 + (f_u)^2 & f_u f_v \\ f_v f_u & 1 + (f_v)^2 \end{pmatrix} \qquad \text{and} \qquad (L_{ij}) = \frac{1}{\sqrt{1 + f_u^2 + f_v^2}} \begin{pmatrix} f_{uu} & f_{uv} \\ f_{vu} & f_{vv} \end{pmatrix},$$

where f_u is the typical shorthand to mean $\frac{\partial f}{\partial u}$. But then $\det(g) = 1 + f_u^2 + f_v^2$, and we find that the Gaussian curvature function on a function graph is

$$K(u,v) = \frac{1}{(1 + f_u^2 + f_v^2)^2} \begin{vmatrix} f_{uu} & f_{uv} \\ f_{vu} & f_{vv} \end{vmatrix} = \frac{f_{uu} f_{vv} - f_{uv}^2}{(1 + f_u^2 + f_v^2)^2}.$$

This result allows us to rephrase the second derivative test in the calculus of a function f from $\mathbb{R}^2$ to $\mathbb{R}$ as follows: if f has continuous second partial derivatives and (u_0, v_0) is a critical point (i.e., $f_u(u_0, v_0) = f_v(u_0, v_0) = 0$), then

1. (u_0, v_0) is a local maximum if $K(u_0, v_0) > 0$ and $f_{uu}(u_0, v_0) < 0$;
2. (u_0, v_0) is a local minimum if $K(u_0, v_0) > 0$ and $f_{uu}(u_0, v_0) > 0$;
3. (u_0, v_0) is a saddle point if $K(u_0, v_0) < 0$;
4. the test is inconclusive if $K(u_0, v_0) = 0$.

In the language we have introduced in this chapter, local minima and local maxima of the function $z = f(u, v)$ are elliptic points, saddle points are hyperbolic points, and points where the second derivative test is inconclusive are either parabolic or planar points.

Example 6.5.5 (Pseudosphere). A *tractrix* is a curve in the plane with parametric equations

$$\vec{x}(t) = (t - \tanh t, \operatorname{sech} t),$$

and it has the x-axis as an asymptote. The *pseudosphere* is defined as half of the surface of revolution of a tractrix about its asymptote. More precisely, we can parametrize the pseudosphere by

$$\vec{X}(u, v) = (\operatorname{sech} v \cos u, \operatorname{sech} v \sin u, v - \tanh v),$$

with $u \in [0, 2\pi)$ and $v \in [0, \infty)$. (See Figure 6.10 for a picture of the tractrix and the pseudosphere.) We leave it as an exercise for the reader to prove that

$$(g_{ij}) = \begin{pmatrix} \operatorname{sech}^2 v & 0 \\ 0 & \tanh^2 v \end{pmatrix} \qquad \text{and} \qquad (L_{ij}) = \begin{pmatrix} \operatorname{sech} v \tanh v & 0 \\ 0 & -\operatorname{sech} v \tanh v \end{pmatrix}.$$

We find that the Gaussian curvature for the pseudosphere is $K = -1$, which motivates the name "pseudosphere" since it is analogous to the unit sphere but with a constant Gaussian curvature of -1 instead of 1.

Proposition 6.5.6. *Let S be a regular oriented surface of class C^2 with Gauss map $n : S \to \mathbb{S}^2$, and let p be a point on S. Call $K(p)$ the Gaussian curvature of S at p, and suppose that $K(p) \neq 0$. Let B_ε be the ball of radius ε around p and define $V_\varepsilon = B_\varepsilon \cap S$. Calling $K(p)$ the Gaussian curvature of S at p, we have*

$$|K(p)| = \lim_{\varepsilon \to 0} \frac{\operatorname{Area}(n(V_\varepsilon))}{\operatorname{Area}(V_\varepsilon)}.$$

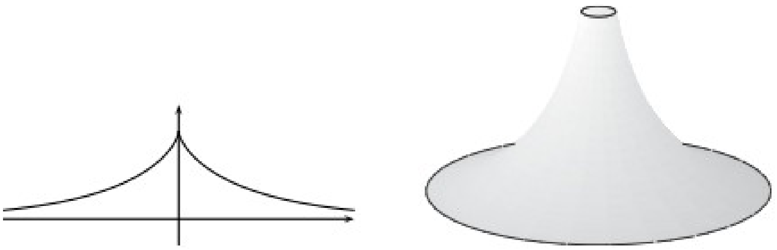


Figure 6.10. Tractrix and pseudosphere.

In other words, the absolute value of the Gaussian curvature at a point p is the limit around p of the ratio of the surface area on $\mathbb{S}^2$ mapped under the Gauss map to the corresponding surface area on S.

Proof: Let $\vec{X} : U \to \mathbb{R}^3$ be a regular parametrization of a neighborhood of $p = \vec{X}(u_0, v_0)$, where U is an open subset of $\mathbb{R}^2$. Since $\vec{X}(U)$ is an open set, $V_\varepsilon \subset \vec{X}(U)$ for all ε small enough. Furthermore, since we assumed that $K(p) \neq 0$, by the continuity of the Gaussian curvature function $K : U \to \mathbb{R}$, we deduce that K does not change sign for ε chosen small enough. Therefore, from now on, we assume that K does not change sign.

Define $U_\varepsilon = \vec{X}^{-1}(V_\varepsilon)$, the preimage of the neighborhood V_ε under $\vec{X}$. Since $\vec{X}$ is bijective as a regular parametrization, $\{(u_0, v_0)\}$ is the unique point in all U_ε for all $\varepsilon > 0$. Then by the formula for surface area,

$$\text{Area}(V_\varepsilon) = \iint_{V_\varepsilon} dA = \iint_{U_\varepsilon} \|\vec{X}_u \times \vec{X}_v\| \, du \, dv.$$

Similarly, on the unit sphere,

$$\text{Area}(n(V_\varepsilon)) = \iint_{U_\varepsilon} \|\vec{N}_u \times \vec{N}_v\| \, du \, dv.$$

However, by Proposition 6.5.2, we also have

$$\text{Area}(n(V_\varepsilon)) = \iint_{U_\varepsilon} |K(u,v)| \|\vec{X}_u \times \vec{X}_v\| \, du \, dv.$$

By the Mean Value Theorem for double integrals, for every $\varepsilon > 0$, there exist points $(u_\varepsilon, v_\varepsilon)$ and $(u'_\varepsilon, v'_\varepsilon)$ in the open set U_ε such that

$$\iint_{U_\varepsilon} \|\vec{X}_u \times \vec{X}_v\|\, du\, dv = \|\vec{X}_u(u_\varepsilon, v_\varepsilon) \times \vec{X}_v(u_\varepsilon, v_\varepsilon)\|$$

and

$$\iint_{U_\varepsilon} \|\vec{N}_u \times \vec{N}_v\|\, du\, dv = |K(u'_\varepsilon, v'_\varepsilon)|\, \|\vec{X}_u(u'_\varepsilon, v'_\varepsilon) \times \vec{X}_v(u'_\varepsilon, v'_\varepsilon)\|.$$

Thus, since $\lim_{\varepsilon\to 0}(u_\varepsilon, v_\varepsilon) = \lim_{\varepsilon\to 0}(u'_\varepsilon, v'_\varepsilon) = (u_0, v_0)$, we have

$$\begin{aligned}\lim_{\varepsilon\to 0}\frac{\text{Area}(n(V_\varepsilon))}{\text{Area}(V_\varepsilon)} &= \lim_{\varepsilon\to 0}\frac{|K(u'_\varepsilon, v'_\varepsilon)|\, \|\vec{X}_u(u'_\varepsilon, v'_\varepsilon) \times \vec{X}_v(u'_\varepsilon, v'_\varepsilon)\|}{\|\vec{X}_u(u_\varepsilon, v_\varepsilon) \times \vec{X}_v(u_\varepsilon, v_\varepsilon)\|} \\ &= \frac{|K(u_0, v_0)|\|\vec{X}_u(u_0, v_0) \times \vec{X}_v(u_0, v_0)\|}{\|\vec{X}_u(u_0, v_0) \times \vec{X}_v(u_0, v_0)\|} \\ &= |K(u_0, v_0)| = |K(p)|. \qquad \square\end{aligned}$$

Problems

6.5.1. Calculate the Gaussian curvature of the torus parametrized by

$$\vec{X}(u, v) = ((a + b\cos v)\cos u, (a + b\cos v)\sin u, b\sin v)$$

where $a > b$ are constants and $(u, v) \in (0, 2\pi) \times (0, 2\pi)$.

6.5.2. Consider a regular space curve $\vec{\gamma} : I \to \mathbb{R}^3$ and the tangential surface defined by

$$\vec{X}(t, u) = \vec{\gamma}(t) + u\vec{\gamma}'(t)$$

for $(t, u) \in I \times \mathbb{R}$. Calculate the mean and Gaussian curvature functions.

6.5.3. Let $\vec{\alpha}(t)$ and $\vec{\beta}(t)$ be differentiable vector functions with common domain I. Define the *secant surface* between the two resulting curves by

$$\vec{X}(t, u) = (1 - u)\vec{\alpha}(t) + u\vec{\beta}(t)$$

for $(t, u) \in I \times \mathbb{R}$. Assume that the corresponding surface is regular.

5- <T2 N3

volve three unknown functions in two variables, they are intractable in general. Nonetheless, we shall study various classes of surfaces that satisfy $K = 0$ or $H = 0$.

Planes satisfy $K = 0$, but other surfaces do as well, for example, cylinders and cones. In a geometric sense, cylinders and cones in fact resemble a plane because, as any elementary school student knows, one can create a cylinder or a cone out of a flat paper without folding, stretching, or crumpling. In the first half of this section, we introduce ruled surfaces and determine the conditions for these ruled surfaces to have Gaussian curvature everywhere 0.

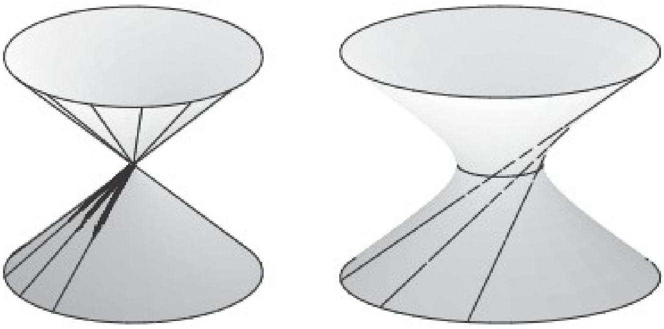
As of yet, we have neither seen a particularly intuitive interpretation of the mean curvature nor have presented surfaces that satisfy $H = 0$. However, as we shall see, surfaces that satisfy $H = 0$ have minimal surface area in the following sense. Given a curve C in $\mathbb{R}^3$, among surfaces S that have $C = \partial S$ as a boundary, a surface with minimal surface area will have mean curvature H everywhere 0. Consequently, a surface that satisfies $H = 0$ is called a *minimal surface*. Many articles and books are devoted to the study of minimal surfaces (see [20], [26], or [25] to name a few; an internet search will reveal many more), so in the interest of space, the second half of this section gives only a brief introduction to minimal surfaces.

6.6.1 Ruled Surfaces

Geometrically, we define a *ruled surface* as the union of a (differentiable) one-parameter family of straight lines in $\mathbb{R}^3$. One can specify each line in the family by a point $\vec{\alpha}(t)$ and by a direction given by another vector $\vec{w}(t)$. The adjective "differentiable" means that both $\vec{\alpha}$ and $\vec{w}$ are differentiable vector functions over some interval $I \subset \mathbb{R}$. We parametrize a ruled surface by

$$\vec{X}(t,u) = \vec{\alpha}(t) + u\,\vec{w}(t), \qquad \text{with } (t,u) \in I \times \mathbb{R}. \tag{6.38}$$

We call the lines L_t passing through $\vec{\alpha}(t)$ with direction $\vec{w}(t)$ the *rulings*, and the curve $\vec{\alpha}(t)$ is called the *directrix* of the surface. We should note that this definition does not insist that ruled surfaces be regular; in particular, we allow singular points, that is, points where $\vec{X}_t \times \vec{X}_u = \vec{0}$.



(a) Cone (b) Hyperboloid

Figure 6.11. Ruled surfaces.

Example 6.6.1 (Cylinders). The simplest example of a ruled surface is a cylinder. The general definition of a cylinder is a ruled surface that can be given as a one-parameter family of lines where the directrix $\vec{\alpha}(t)$ is planar and $\vec{w}(t)$ is a constant vector in $\mathbb{R}^3$.

Example 6.6.2 (Cones). The general definition of a cone is a surface that can be given as a one-parameter family of lines where the directrix $\vec{\alpha}(t)$ lies in a plane P and the rulings L_t all pass through some common point $p \notin P$. Therefore, the cone over $\vec{\alpha}(t)$ through p can be parametrized by

$$\vec{X}(t,u) = \vec{\alpha}(t) + u(p - \vec{\alpha}(t)).$$

Example 6.6.3. As a perhaps initially surprising example, the hyperboloid of one sheet is also a ruled surface. The standard parametrization for the hyperboloid of one sheet is

$$\vec{X}(u,v) = (\cosh v \cos u, \cosh v \sin u, \sinh v).$$

Consider alternatively the ruled surface given by the directrix $\vec{\alpha}(t) = (\cos t, \sin t, 0)$, with ruling directions $\vec{w}(t) = \vec{\alpha}'(t) + \vec{k} = (-\sin t, \cos t, 1)$ (see Figure 6.11(b)). We obtain the parametrized surface

$$\vec{Y}(t,u) = (\cos t - u\sin t, \sin t + u\cos t, u).$$

Though it is not particularly easy to express $\vec{Y}$ as a reparametrization of $\vec{X}$, it is not hard to see that both of these parametrizations satisfy the following usual equation that gives the hyperboloid as a conic surface:

$$x^2 + y^2 - z^2 = 1.$$

We will determine the Gaussian curvature for ruled surfaces, but, for the purposes of subsequent calculations, we make two simplifications. First, note that one can impose the condition that $\|\vec{w}(t)\| = 1$ without changing the definition or the image of the parametrization in Equation (6.38). In defining particular ruled surfaces, it is usually easier not to make this assumption, but it does simplify calculations since $\|\vec{w}(t)\| = 1$ for all $t \in I$ implies that $\vec{w}(t) \cdot \vec{w}(t)' = 0$. Secondly, note that different curves $\vec{\alpha}(t)$ can serve as the directrix for the same ruled surface, so we wish to employ a curve $\vec{\beta}(t)$ as a directrix, which will simplify the algebra in our calculations. We choose a curve $\vec{\beta}(t)$ satisfying $\vec{\beta}'(t) \cdot \vec{w}'(t) = 0$.

Since $\vec{\beta}(t)$ lies on $\vec{X}$, we can write

$$\vec{\beta}(t) = \vec{\alpha}(t) + u(t)\vec{w}(t). \tag{6.39}$$

Then

$$\vec{\beta}'(t) = \vec{\alpha}'(t) + u'(t)\vec{w}(t) + u(t)\vec{w}'(t),$$

and since $\vec{\beta}' \cdot \vec{w}' = 0$, we have

$$\vec{\alpha}'(t) \cdot \vec{w}'(t) + u(t)\vec{w}'(t) \cdot \vec{w}'(t) = 0.$$

Thus, we determine that

$$u(t) = -\frac{\vec{\alpha}'(t) \cdot \vec{w}'(t)}{\|\vec{w}'(t)\|^2}. \tag{6.40}$$

Furthermore, it is easy to prove (see Problem 6.6.3) that, with our present assumptions, $\vec{\beta}(t)$ is unique. We call the curve $\vec{\beta}(t)$ the *line of stricture* of the ruled surface.

We now use the parametrization for the ruled surface $\vec{X} = \vec{\beta}(t) + u\vec{w}(t)$ and proceed to calculate the first and second fundamental forms. Understanding that $\vec{\beta}$ and $\vec{w}$ are functions of t, we find that

$$\begin{aligned} \vec{X}_t &= \vec{\beta}' + u\,\vec{w}', & & & \vec{X}_{tt} &= \vec{\beta}'' + u\,\vec{w}'', \\ \vec{X}_u &= \vec{w}, & &\text{and} & \vec{X}_{tu} &= \vec{w}', \\ \vec{X}_t \times \vec{X}_u &= \vec{\beta}' \times \vec{w} + u\,\vec{w}' \times \vec{w}, & & & \vec{X}_{uu} &= \vec{0}. \end{aligned}$$

One can already notice that if $\vec{w}(t)$ is constant, then $L_{12} = L_{21} = L_{22} = 0$, which leads to $K = 0$ and proves that all cylinders have Gaussian curvature $K = 0$. We will assume now that $\vec{w}'(t)$ is not identically 0.

Because of the conditions $\vec{w} \cdot \vec{w}' = 0$ and $\vec{\beta}' \cdot \vec{w}' = 0$, we can conclude that $\vec{\beta}' \times \vec{w}$ is parallel to $\vec{w}'$. Thus, $\vec{\beta}' \times \vec{w}$ is perpendicular to $\vec{w} \times \vec{w}'$, so

$$\|\vec{X}_t \times \vec{X}_u\|^2 = \|\vec{\beta}' \times \vec{w}\|^2 + u^2\|\vec{w}'\|^2.$$

Furthermore, $\vec{\beta}' \times \vec{w} = (\vec{\beta}' \times \vec{w}) \cdot \vec{w}'/\|\vec{w}'\|$ and hence,

$$\begin{aligned} \|\vec{X}_t \times \vec{X}_u\|^2 &= (\vec{\beta}'\vec{w}\vec{w}')^2/\|\vec{w}'\|^2 + u^2\|\vec{w}'\|^2 && (6.41)\\ &= \frac{1}{\|\vec{w}'\|^2}\left((\vec{\beta}'\vec{w}\vec{w}')^2 + u^2\|\vec{w}'\|^4\right), && (6.42)\end{aligned}$$

where we use the notation $(\vec{\beta}'\vec{w}\vec{w}')$ for $(\vec{\beta}' \times \vec{w}) \cdot \vec{w}'$, the triple-vector product in $\mathbb{R}^3$. Consequently, we can write the unit normal vector $\vec{N}$ as

$$\vec{N}(t,u) = \frac{\|\vec{w}'\|}{\sqrt{(\vec{\beta}'\vec{w}\vec{w}')^2 + u^2\|\vec{w}'\|^4}}\left(\vec{\beta}' \times \vec{w} + u\,\vec{w}' \times \vec{w}\right), \qquad (6.43)$$

and therefore, again using the conditions that $\vec{w} \cdot \vec{w}' = 0$ and $\vec{\beta}' \cdot \vec{w}' = 0$, we get

$$(g_{ij}) = \begin{pmatrix} \|\vec{\beta}'\|^2 + u^2\|\vec{w}'\|^2 & 0 \\ 0 & 1 \end{pmatrix} \qquad (6.44)$$

and

$$(L_{ij}) = \frac{\|\vec{w}'\|}{\sqrt{(\vec{\beta}'\vec{w}\vec{w}')^2 + u^2\|\vec{w}'\|^4}}\begin{pmatrix} (\vec{\beta}'' + u\vec{w}'') \cdot (\vec{\beta}' \times \vec{w} + u\vec{w}' \times \vec{w}) & (\vec{\beta}'\vec{w}\vec{w}') \\ (\vec{\beta}'\vec{w}\vec{w}') & 0 \end{pmatrix}. \qquad (6.45)$$

We cannot say much for the entry L_{11}, but thanks to Equation (6.37) for the Gaussian curvature and the fact that $\|\vec{X}_u \times \vec{X}_v\|^2 = \det(g_{ij})$ (see Equation (6.6)), one can calculate the Gaussian curvature for a ruled surface as

$$K = \frac{\det(L_{ij})}{\det(g_{ij})} = -\frac{\|\vec{w}'\|^4(\vec{\beta}'\vec{w}\vec{w}')^2}{\left((\vec{\beta}'\vec{w}\vec{w}')^2 + u^2\|\vec{w}'\|^4\right)^2}. \qquad (6.46)$$

This formula for the Gaussian curvature of a ruled surface makes a few facts readily apparent. First, $K \leq 0$ for all points of a ruled surface. Secondly, by Equation (6.41), all of the singular points of a ruled surface, i.e., points where $\vec{X}_t \times \vec{X}_u = \vec{0}$, must have $u = 0$ and therefore occur on the line of stricture. Finally, we see that a noncylindrical ruled surface satisfies $K(t, u) = 0$ if and only if $(\vec{\beta}'\vec{w}\vec{w}') = 0$ for all $t \in I$.

Let us return now to the general definition of a ruled surface from Equation (6.38) with regular curves $\vec{\alpha}(t)$ and $\vec{w}(t)$ with no conditions. Since both $\vec{w}$ and $\vec{w}'$ are perpendicular to $\vec{w} \times \vec{w}'$,

$$(\vec{\alpha}'\vec{w}\vec{w}') = \vec{\alpha}' \cdot (\vec{w} \times \vec{w}') = \vec{\beta}' \cdot (\vec{w} \times \vec{w}') = (\vec{\beta}'\vec{w}\vec{w}').$$

Furthermore, if we call $\hat{w} = \vec{w}/\|\vec{w}\|$, we remark that

$$(\vec{\alpha}'\vec{w}\vec{w}') = \|w\|^2(\vec{\alpha}'\hat{w}\hat{w}') = \|w\|^2(\vec{\beta}'\hat{w}\hat{w}').$$

Consequently, $(\vec{\beta}'\hat{w}\hat{w}') = 0$ if and only if $(\vec{\alpha}'\vec{w}\vec{w}') = 0$.

The ruled surface $\vec{X}(t, u)$ is called a *developable surface* if $(\vec{\alpha}'\vec{w}\vec{w}') = 0$. Equation (6.46) shows that all developable surfaces have Gaussian curvature identically 0. This result provides us with a class of surfaces that satisfy $K = 0$, though it by no means proves whether $K = 0$ implies that a surface is developable.

It is interesting to remark that a ruled surface is a cone if and only if $\vec{\alpha}'(t) = 0$ and is a cylinder if and only if $\vec{w}'(t) = 0$, showing again that both cones and cylinders are developable and have $K = 0$. The exercises present examples of developable surfaces that are neither cones nor cylinders.

6.6.2 Minimal Surfaces

Definition 6.6.4. A *minimal surface* is a parametrized surface of class C^2 that satisfies the regularity condition and for which the mean curvature is identically 0.

We first wish to justify the name "minimal." Let $\vec{X} : U \to \mathbb{R}^3$ be a coordinate neighborhood of a regular parametrized surface of class C^2. Let D' be a connected compact set in U, and let $D = \vec{X}(D')$. Let $h : U \to \mathbb{R}$ be a differentiable function. A normal variation of

$\vec{X}$ over D' determined by h is the family of surfaces with $t \in (-\varepsilon, \varepsilon)$ defined by

$$\begin{aligned} \vec{X}^t : D' &\longrightarrow \mathbb{R}^3 \\ (u,v) &\longmapsto \vec{X}(u,v) + th(u,v)\vec{N}(u,v). \end{aligned} \tag{6.47}$$

Proposition 6.6.5. *Let $\vec{X}^t$ be a normal variation of $\vec{X}$ over a compact region D' and determined by some function h. For ε small enough, $\vec{X}^t$ satisfies the regularity condition for all $t \in (-\varepsilon, \varepsilon)$. In this case, the area of $\vec{X}^t$ is*

$$A(t) = \iint_{D'} \sqrt{1 - 4thH + t^2 R}\sqrt{\det(g_{ij})}\, du\, dv \tag{6.48}$$

for some function $R(u,v,t)$ that is polynomial in t.

Proof: Denote g_{ij}^t as the coefficients of the metric tensor. The surfaces of the normal variation have

$$\begin{aligned} \vec{X}_u^t &= \vec{X}_u + th_u\vec{N} + th\vec{N}_u, \\ \vec{X}_v^t &= \vec{X}_v + th_v\vec{N} + th\vec{N}_v. \end{aligned}$$

Thus, we calculate,

$$\begin{aligned} g_{11}^t &= g_{11} + 2th\vec{X}_u \cdot \vec{N}_u + t^2h^2\vec{N}_u \cdot \vec{N}_u + t^2h_u^2, \\ g_{12}^t &= g_{12} + th(\vec{X}_u \cdot \vec{N}_v + \vec{X}_v \cdot \vec{N}_u) + t^2h^2\vec{N}_u \cdot \vec{N}_v + t^2h_uh_v, \\ g_{22}^t &= g_{22} + 2th\vec{X}_v \cdot \vec{N}_v + t^2h^2\vec{N}_v \cdot \vec{N}_v + t^2h_v^2. \end{aligned}$$

However, by Equation (6.16), one can summarize the above equations as

$$g_{ij}^t = g_{ij} - 2thL_{ij} + t^2h^2\vec{N}_i \cdot \vec{N}_j + t^2h_ih_j,$$

where we use the notation h_1 (respectively h_2) to indicate the partial derivative h_u (respectively h_v). Therefore, we calculate that

$$\det(g_{ij}^t) = \det(g_{ij}) - 2th(g_{11}L_{22} - 2g_{12}L_{12} + g_{22}L_{11}) + t^2\bar{R},$$

where $\bar{R}(u,v,t)$ is a function of the form $A_0(u,v) + tA_1(u,v) + t^2A_2(u,v)$ for continuous functions A_i defined over D'. However, the mean curvature is

$$H = \frac{1}{2}\frac{g_{11}L_{22} - 2g_{12}L_{12} + g_{22}L_{11}}{g_{11}g_{22} - g_{12}^2},$$

which leads to

$$\det(g_{ij}^t) = \det(g_{ij})(1 - 4thH) + t^2\bar{R} = \det(g_{ij})(1 - 4thH + t^2R), \tag{6.49}$$

where $R = \bar{R}/\det(g_{ij})$. Since D' is compact, the functions h, H, and R are bounded over D', which shows that

$$\lim_{t\to 0} \det(g_{ij}^t) = \det(g_{ij}) \quad \text{for all } (u, v) \in D'.$$

Hence, if $\varepsilon > 0$ is small enough, then $\det(g_{ij}^t) \neq 0$ for all $t \in (-\varepsilon, \varepsilon)$, and thus, all normal variations satisfy the regularity condition. The rest of the proposition follows from Equation (6.49) since

$$A(t) = \iint\limits_{D'} \sqrt{\det(g_{ij}^t)}\, du\, dv.$$

□

Proposition 6.6.6. *Let $\vec{X} : U \to \mathbb{R}^3$ be a parametrized surface of class C^2, and let $D' \in U$ be a compact set. Let $A(t)$ be the area function defined in Equation (6.48). Then $\vec{X}$ parametrizes a minimal surface if and only if $A'(0) = 0$ for all D' and all normal variations of $\vec{X}$ over D'.*

Proof: We calculate

$$A'(t) = \iint\limits_{D'} \frac{-4hH + 2tR + t^2R_t}{2\sqrt{1 - 4thH + t^2R}} \sqrt{\det(g_{ij})}\, du\, dv,$$

which implies that

$$A'(0) = -2 \iint\limits_{D'} hH \sqrt{\det(g_{ij})}\, du\, dv.$$

Obviously, if $\vec{X}$ parametrizes a minimal surface, which means that $H = 0$ for all $(u, v) \in U$, then $A'(0) = 0$ regardless of the function $h(u, v)$ or the compact set D'.

To prove the converse, suppose that $A'(0) = 0$ for all continuous functions $h(u, v)$ and all compact $D' \subset U$. Choosing $h(u, v) = H(u, v)$, since $\det(g_{ij}) > 0$, we have

$$A'(0) = -2 \iint\limits_{D'} H^2 \sqrt{\det(g_{ij})}\, du\, dv,$$

so $A'(0) \leq 0$ for all choices of D'. Since $H(u,v)$ is continuous, if $H(u_0,v_0) \neq 0$ for any point (u_0,v_0), there is a compact set D' containing (u_0,v_0) such that $H(u,v)^2 > 0$ over D'. Thus, if H is anywhere nonzero, there exists a compact subset D' such that $A'(0) < 0$. This is a contradiction, so we conclude that $A'(0) = 0$ for all h and all D' implies that $H(u,v) = 0$ for all $(u,v) \in U$. □

Proposition 6.6.6 shows that a parametrized surface $\vec{X}$ that satisfies the regularity condition $\|\vec{X}_u \times \vec{X}_u\| \neq 0$ is minimal (has $H = 0$ everywhere) if it is a surface such that over every patch of surface there is no way to deform it along normal vectors to obtain a surface of lesser surface area.

Minimal surfaces have enjoyed considerable popular attention, especially in museums of science, as soap films on a wire frame. When a wire frame is dipped into a soapy liquid and pulled out, the surface tension on the soap film pulls the film into the state of least potential energy, which turns out to be the surface such that no normal variation can lead to a surface with less surface area. Of course, when experimenting with soap films, one can experiment with wire frames that are nonregular curves or not even curves at all (the skeleton of a cube, for example) and investigate what kinds of soap film surfaces result.

The problem of determining a minimal surface with a given closed regular space curve C as a boundary was raised by Lagrange in 1760. However, the mathematical problem became known as Plateau's problem, named after Joseph Plateau who specifically studied soap film surfaces. The nineteenth century saw a few specialized solutions to the problem, but it was not solved until 1930. (See [25] for a more complete history of Plateau's problem.)

Though one can easily construct a minimal surface with a soap film on a wire frame, either checking that a surface is minimal or finding a parametrization for a minimal surface is quite difficult. In fact, the study of minimal surfaces continues to provide new areas of research and connections with other branches of analysis. Perhaps among the most interesting results is a connection between complex analytic functions and minimal surfaces [10, p. 206] or the use of elliptic integrals to parametrize special minimal surfaces [25, Chapter 1], topics that go beyond the scope of this book. However, it is quite likely that having both the simple experimentative aspect and connections to advanced mathematics has fueled interest in minimal surfaces.

Problems

6.6.1. Prove that the surface given by $z = kxy$, where k is a constant, is a ruled surface and give it as a one-parameter family of lines.

6.6.2. The tangential surface to a space curve $\vec{\alpha}(t)$ was presented in Problem 6.5.2. Show that the curve $\vec{\alpha}$ is the line of stricture for the tangential surface. Show that the tangential surface to a regular space curve is a developable surface.

6.6.3. Suppose that $\{\vec{\alpha}_1(t), \vec{w}(t)\}$ and $\{\vec{\alpha}_2(t), \vec{w}(t)\}$, where $\|\vec{w}(t)\| = 1$, are two one-parameter families of lines that trace out the same ruled surface. Prove that Equation (6.39) with, (6.40), using either $\vec{\alpha}_1$ or $\vec{\alpha}_2$, produce the same line of stricture.

6.6.4. Let S be an orientable surface, and let $\vec{\alpha}(s)$ be a curve on S parametrized by arc length. Assume that $\vec{\alpha}$ is nowhere tangent to the asymptotic direction on S, and define $\vec{N}(s)$ as the unit normal vector to S along $\vec{\alpha}(s)$. Consider the ruled surface

$$\vec{X}(s, u) = \vec{\alpha}(s) + u\,\frac{\vec{N}(s) \times \vec{N}'(s)}{\|\vec{N}'(s)\|}.$$

The assumption that $\vec{\alpha}'(s)$ is not an asymptotic direction ensures that $\vec{N}'(s) \neq \vec{0}$. Prove that $\vec{X}(s, v)$ is a developable surface. (This kind of surface is called the *envelope* of a family of tangent planes along a curve of a surface.)

6.6.5. Show that a surface $F(x, y, z) = 0$ is developable if

$$\begin{vmatrix} F_{xx} & F_{xy} & F_{xz} & F_x \\ F_{yx} & F_{yy} & F_{yz} & F_y \\ F_{zx} & F_{zy} & F_{zz} & F_z \\ F_x & F_y & F_z & 0 \end{vmatrix} = 0.$$

6.6.6. Let $\vec{X}(t, v) = \vec{\alpha}(t) + v\vec{w}(t)$ be a developable surface. Prove that at a regular point

$$\vec{N}_v \cdot \vec{X}_t = 0 \qquad \text{and} \qquad \vec{N}_v \cdot \vec{X}_v = 0.$$

Use this result to prove that the tangent plane of a developable surface is constant along a line of ruling.

5- 6/2 N 3

7.2.6. *Tubes*. Let $\vec{\alpha}(t)$ be a regular space curve and let r be small enough that the tube

$$\vec{X}(t,u) = \vec{\alpha}(t) + (r\cos u)\vec{P}(t) + (r\sin u)\vec{B}(t)$$

is a regular surface. Calculate the Christoffel symbols for the tube $\vec{X}$.

7.2.7. Prove that a parametrization $\vec{X}$ of a neighborhood on a surface S is such that all the coordinate lines $x^2 = c$ are asymptotic lines if and only if $L_{11} = 0$.

7.2.8. Defining the function $D(x^1, x^2)$ as $D^2 = \det(g_{ij})$, show that

$$\frac{\partial}{\partial x^1}(\ln D) = \Gamma^1_{11} + \Gamma^2_{12} \qquad \text{and} \qquad \frac{\partial}{\partial x^2}(\ln D) = \Gamma^1_{12} + \Gamma^2_{22}.$$

7.2.9. Suppose that S is a surface with a parametrization that satisfies $\Gamma^1_{12} = \Gamma^2_{12} = 0$. Prove that S is a translation surface.

7.2.10. Using D as defined in Problem 7.2.8, calling $\theta(x^1, x^2)$ the angle between the coordinate lines, prove that

$$\frac{\partial\theta}{\partial x^1} = -\frac{D}{g_{11}}\Gamma^2_{11} - \frac{D}{g_{22}}\Gamma^2_{11} \quad \text{and} \quad \frac{\partial\theta}{\partial x^2} = -\frac{D}{g_{11}}\Gamma^2_{12} - \frac{D}{g_{22}}\Gamma^1_{22}. \quad (7.40)$$

Show that if the parametrization is orthogonal, i.e., $g_{12} = 0$, Equation (7.40) becomes

$$g_{22}\Gamma^2_{11} + g_{11}\Gamma^1_{12} = 0 \qquad \text{and} \qquad g_{22}\Gamma^2_{12} + g_{11}\Gamma^1_{22} = 0.$$

7.3 Codazzi Equations and the Theorema Egregium

The Gauss equations in Equation (7.29) define expressions for any second derivative $\vec{X}_{ij}$ in terms of the coefficients of the first and second fundamental forms and the basis $\{\vec{X}_1, \vec{X}_2, \vec{N}\}$. We remind the reader that the symmetry of the dot product imposes $g_{ij} = g_{ji}$. Furthermore, from $\vec{X}_{ij} = \vec{X}_{ji}$, we also deduced that $L_{ij} = L_{ji}$.

Definition 5.2.9 of a regular surface imposes the condition that all the higher derivatives of any parametrization $\vec{X}$ of a coordinate patch be continuous for all higher derivatives. Therefore, for a regular parametrization, the order in which one takes derivatives with respect to given variables is irrevelant. In particular, for the mixed third derivatives, we have $\vec{X}_{112} = \vec{X}_{121}$ and $\vec{X}_{221} = \vec{X}_{122}$, which can be listed in the following slightly more suggestive manner:

$$\frac{\partial \vec{X}_{11}}{\partial x^2} = \frac{\partial \vec{X}_{12}}{\partial x^1} \quad \text{and} \quad \frac{\partial \vec{X}_{22}}{\partial x^1} = \frac{\partial \vec{X}_{12}}{\partial x^2}$$

Consequently, because of the nontrivial expressions in Gauss's equations, we obtain

$$\begin{aligned} \frac{\partial}{\partial x^2}\left(\Gamma_{11}^1 \vec{X}_1 + \Gamma_{11}^2 \vec{X}_2 + L_{11}\vec{N}\right) &= \frac{\partial}{\partial x^1}\left(\Gamma_{12}^1 \vec{X}_1 + \Gamma_{12}^2 \vec{X}_2 + L_{12}\vec{N}\right), \\ \frac{\partial}{\partial x^2}\left(\Gamma_{12}^1 \vec{X}_1 + \Gamma_{12}^2 \vec{X}_2 + L_{12}\vec{N}\right) &= \frac{\partial}{\partial x^1}\left(\Gamma_{22}^1 \vec{X}_1 + \Gamma_{22}^2 \vec{X}_2 + L_{22}\vec{N}\right). \end{aligned} \tag{7.41}$$

It is natural to equate the basis components of each equation. However, when we take the partial derivatives, we will obtain expressions involving second derivatives of $\vec{X}$ and derivatives of $\vec{N}$ that we need to put back into the usual $\{\vec{X}_1, \vec{X}_2, \vec{N}\}$ basis using the Weingarten equations given in Equation (6.26) or Gauss's equations in Equation (7.29). Doing this transforms Equation (7.41) into six distinct equations from which we deduce two significant theorems in the theory of surfaces.

Theorem 7.3.1 (Codazzi Equations). *For any parametrized smooth surface, the following hold:*

$$\begin{aligned} \frac{\partial L_{11}}{\partial x^2} - \frac{\partial L_{12}}{\partial x^1} &= L_{11}\Gamma_{12}^1 + L_{12}\Gamma_{12}^2 - L_{12}\Gamma_{11}^1 - L_{22}\Gamma_{11}^2, \\ \frac{\partial L_{12}}{\partial x^2} - \frac{\partial L_{22}}{\partial x^1} &= L_{11}\Gamma_{22}^1 + L_{12}\Gamma_{22}^2 - L_{12}\Gamma_{12}^1 - L_{22}\Gamma_{12}^2. \end{aligned} \tag{7.42}$$

We can summarize these two equations in one by

$$\frac{\partial L_{ij}}{\partial x^l} - \Gamma_{il}^k L_{kj} = \frac{\partial L_{il}}{\partial x^j} - \Gamma_{ij}^k L_{kl} \tag{7.43}$$

for all $1 \le i, j, l \le 2$, where Einstein summation is implied.

Proof: Equate the $\vec{N}$ coefficient functions in both equations from Equation (7.41). □

The classical formulation of the above relationships in Equation (7.42) are collectively called the Codazzi equations or sometimes the Mainardi-Codazzi equations. These equations present a relationship that must hold between the coefficients of the first and second fundamental form that must hold for all regular surfaces. They are a crucial part of the Fundamental Theorem of Surface Theory that we will present in Section 7.4.

The following theorem is another result that stems from equating components along $\vec{X}_1$ and $\vec{X}_2$ in Equation (7.41).

Theorem 7.3.2 (Theorema Egregium). *The Gaussian curvature of a surface is an intrinsic property of the surface, that is, it depends only on the coefficients of the metric tensor and higher derivatives thereof.*

Proof: Equating the $\vec{X}_1$ and $\vec{X}_2$ coefficient functions in the first equation of Equation (7.41), we obtain

$$\frac{\partial \Gamma_{11}^1}{\partial x^2} + \Gamma_{11}^1\Gamma_{12}^1 + \Gamma_{11}^2\Gamma_{22}^1 + L_{11}a_2^1 = \frac{\partial \Gamma_{12}^1}{\partial x^1} + \Gamma_{12}^1\Gamma_{11}^1 + \Gamma_{12}^2\Gamma_{12}^1 + L_{12}a_1^1,$$
$$\frac{\partial \Gamma_{11}^2}{\partial x^2} + \Gamma_{11}^1\Gamma_{12}^2 + \Gamma_{11}^2\Gamma_{22}^2 + L_{11}a_2^2 = \frac{\partial \Gamma_{12}^2}{\partial x^1} + \Gamma_{12}^1\Gamma_{11}^2 + \Gamma_{12}^2\Gamma_{12}^2 + L_{12}a_1^2.$$

Since $a_j^i = -\sum_{l=1}^2 L_{jl}g^{li}$, where $(g^{ij}) = (g_{ij})^{-1}$, after some simplification, we can write these two equations as

$$g_{21}\frac{L_{11}L_{22} - (L_{12})^2}{\det g} = \frac{\partial \Gamma_{12}^1}{\partial x^1} - \frac{\partial \Gamma_{11}^1}{\partial x^2} + \Gamma_{12}^2\Gamma_{12}^1 - \Gamma_{11}^2\Gamma_{22}^1, \quad (7.44)$$

$$\begin{aligned} -g_{11}\frac{L_{11}L_{22} - (L_{12})^2}{\det g} &= \frac{\partial \Gamma_{12}^2}{\partial x^1} - \frac{\partial \Gamma_{11}^2}{\partial x^2} + \Gamma_{12}^1\Gamma_{11}^2 + \Gamma_{12}^2\Gamma_{12}^2 \\ &\quad - \Gamma_{11}^1\Gamma_{12}^2 - \Gamma_{11}^2\Gamma_{22}^2. \end{aligned} \quad (7.45)$$

Since $K = \det(L_{ij})/\det(g_{ij})$, we can use either one of these equations to obtain a formula for K in terms of the function g_{ij} and Γ_{jk}^i. However, since the Christoffel symbols Γ_{jk}^i are themselves determined by the coefficients of the metric tensor, then these equations provide formulas for the Gaussian curvature exclusively in terms of the first fundamental form. □

Gauss coined the name "Theorema Egregium," which means "an excellent theorem," and indeed this result should seem rather surprising. A priori, the Gaussian curvature depends on the commponents of the first fundamental form and the second fundamental form. After all, the Gaussian curvature at a point p on the surface is $K = \det(dn_p)$, where dn_p is the differential of the Gauss map. Since the coefficients of the matrix dn_p with respect to the basis $\{\vec{X}_1, \vec{X}_2\}$ involve the L_{ij} coefficients, one would naturally expect that we would need the second fundamental form to calculate K. However, the Theorema Egregium shows that only the coefficient functions of the first fundamental form are necessary.

In the study of surfaces, we called a local or a global property of a curve or surface a "geometric quantity" if it does not change under the orientation and position of the curve or surface in space. On the other hand, topology studies properties of point sets that are invariant under any homeomorphism—a bijective function that is continuous in both directions. The concept of an intrinsic property lies somewhere between these two extremes. Intrinsic geometry studies what some mathematicians classically call "bending invariants," quantities that are preserved when one bends the curve or surface but does not stretch them.

In the above proof, Equations (7.44) and (7.45) motivate the following definition of the *Riemann symbols*:

$$R^l_{ijk} = \frac{\partial \Gamma^l_{ik}}{\partial x^j} - \frac{\partial \Gamma^l_{jk}}{\partial x^i} + \Gamma^m_{ik}\Gamma^l_{mj} - \Gamma^m_{jk}\Gamma^l_{mi}. \tag{7.46}$$

As it turns out (see Problem 7.3.2), the Riemann symbols form the components of a $(1,3)$-tensor. Then, a closely associated tensor denoted by

$$R_{ijkl} = R^m_{ijk} g_{ml} \tag{7.47}$$

has the interesting property that $R_{1212} = \det(L_{ij})$, and hence, the Gaussian curvature of a surface at a point is given by the component function

$$K = \frac{R_{1212}}{\det(g_{ij})}. \tag{7.48}$$

The tensor associated to the components R^l_{ijk} is called the Riemann curvature tensor and plays an important role in the analysis on manifolds.

Example 7.3.3 (Cone). As a simple example, consider the right circular cone defined by the parametrization

$$\vec{X}(u,v) = (v\cos u, v\sin u, v),$$

where $u \in [0, 2\pi]$ and $v > 0$, which we know, as a developable surface, has Gaussian curvature $K = 0$ everywhere. Simple calculations give, for the metric tensor,

$$g_{11} = v^2, \qquad g_{12} = 0, \qquad g_{22} = 2.$$

For the Christoffel symbols, one obtains

$$\Gamma_{11}^2 = -\frac{1}{2}v, \qquad \Gamma_{12}^1 = \Gamma_{21}^1 = \frac{1}{v}$$

with all the other symbols of the second kind $\Gamma_{jk}^i = 0$. With this data, an application of Equation (7.46) shows that all but two of the Riemann symbols vanish simply because all the terms vanish. However, for the two nontrivial terms, one calculates

$$R_{122}^1 = \frac{\partial \Gamma_{12}^1}{\partial v} - \frac{\partial \Gamma_{22}^1}{\partial u} + \Gamma_{12}^1\Gamma_{12}^1 + \Gamma_{12}^2\Gamma_{22}^1 - \Gamma_{22}^1\Gamma_{11}^1 - \Gamma_{22}^2\Gamma_{21}^1 = -\frac{1}{v^2} + \frac{1}{v^2} = 0,$$
$$R_{121}^2 = \frac{\partial \Gamma_{11}^2}{\partial v} - \frac{\partial \Gamma_{12}^2}{\partial u} + \Gamma_{11}^1\Gamma_{12}^2 + \Gamma_{11}^2\Gamma_{22}^2 - \Gamma_{21}^1\Gamma_{11}^2 - \Gamma_{21}^2\Gamma_{21}^2 = -\frac{1}{2} - \left(\frac{1}{v}\right)\left(-\frac{1}{2}v\right) = 0.$$

Consequently, though the Christoffel symbols are not identically 0, the Riemann curvature tensor is identically 0. One finds then that $R_{1212} = 0$ as a function of u and v, and hence, using Equation (7.48), one recovers the fact that the cone has Gaussian curvature identically 0 everywhere.

The Theorema Egregium (Theorem 7.3.2) excited the mathematics community in the middle of the nineteenth century and sparked a search for a variety of alternative formulations for the Gaussian curvature of a surface as a function of the g_{ij} metric coefficients. We leave a few such formulas for K for the exercises, but we present a few here.

Recall that $L_{ij} = \vec{X}_{ij} \cdot \vec{N}$, $\det(g_{ij}) = \|\vec{X}_u \times \vec{X}_v\|^2$, and $\vec{N} = \vec{X}_u \times \vec{X}_v / \|\vec{X}_u \times \vec{X}_v\|$. From these facts, one can easily see that

$$K = \frac{L_{11}L_{22} - L_{12}^2}{\det(g_{ij})} = \frac{(\vec{X}_{uu}\vec{X}_u\vec{X}_v)(\vec{X}_{vv}\vec{X}_u\vec{X}_v) - (\vec{X}_{uv}\vec{X}_u\vec{X}_v)^2}{\det(g_{ij})^2}, \quad (7.49)$$

where $(\vec{A}\vec{B}\vec{C})$ is the triple-vector product in $\mathbb{R}^3$. However, the triple-vector product is a determinant and we know that for all matrices M_1

and M_2, one has $\det(M_1M_2) = \det(M_1)\det(M_2)$, and so Equation (7.49) becomes

$$K = \frac{1}{\det(g_{ij})^2}\left(\begin{vmatrix} \vec{X}_{uu}\cdot\vec{X}_{vv} & \vec{X}_{uu}\cdot\vec{X}_u & \vec{X}_{uu}\cdot\vec{X}_v \\ \vec{X}_u\cdot\vec{X}_{vv} & \vec{X}_u\cdot\vec{X}_u & \vec{X}_u\cdot\vec{X}_v \\ \vec{X}_v\cdot\vec{X}_{vv} & \vec{X}_v\cdot\vec{X}_u & \vec{X}_v\cdot\vec{X}_v \end{vmatrix} - \begin{vmatrix} \vec{X}_{uv}\cdot\vec{X}_{uv} & \vec{X}_{uv}\cdot\vec{X}_u & \vec{X}_{uv}\cdot\vec{X}_v \\ \vec{X}_u\cdot\vec{X}_{uv} & \vec{X}_u\cdot\vec{X}_u & \vec{X}_u\cdot\vec{X}_v \\ \vec{X}_v\cdot\vec{X}_{uv} & \vec{X}_v\cdot\vec{X}_u & \vec{X}_v\cdot\vec{X}_v \end{vmatrix}\right). \quad (7.50)$$

This equation involves only the metric tensor coefficients and Γ^i_{jk} symbols, except in the inner products $\vec{X}_{uu}\cdot\vec{X}_{vv}$ and $\vec{X}_{uv}\cdot\vec{X}_{uv}$. At first glance, this problem seems insurmountable, but if one performs the Laplace expansion on the determinants along the first row, factors terms involving $\det(g_{ij})$, and collects into determinants again, one can show that Equation (7.50) is equivalent to

$$K = \frac{1}{\det(g_{ij})^2}\left(\begin{vmatrix} \vec{X}_{uu}\cdot\vec{X}_{vv} - \vec{X}_{uv}\cdot\vec{X}_{uv} & \vec{X}_{uu}\cdot\vec{X}_u & \vec{X}_{uu}\cdot\vec{X}_v \\ \vec{X}_u\cdot\vec{X}_{vv} & \vec{X}_u\cdot\vec{X}_u & \vec{X}_u\cdot\vec{X}_v \\ \vec{X}_v\cdot\vec{X}_{vv} & \vec{X}_v\cdot\vec{X}_u & \vec{X}_v\cdot\vec{X}_v \end{vmatrix} - \begin{vmatrix} 0 & \vec{X}_{uv}\cdot\vec{X}_u & \vec{X}_{uv}\cdot\vec{X}_v \\ \vec{X}_u\cdot\vec{X}_{uv} & \vec{X}_u\cdot\vec{X}_u & \vec{X}_u\cdot\vec{X}_v \\ \vec{X}_v\cdot\vec{X}_{uv} & \vec{X}_v\cdot\vec{X}_u & \vec{X}_v\cdot\vec{X}_v \end{vmatrix}\right). \quad (7.51)$$

The value in this is that though one cannot express $\vec{X}_{uu}\cdot\vec{X}_{vv}$ or $\vec{X}_{uv}\cdot\vec{X}_{uv}$ using only the metric coefficients, it can be shown that

$$\vec{X}_{uu}\cdot\vec{X}_{vv} - \vec{X}_{uv}\cdot\vec{X}_{uv} = -\frac{1}{2}g_{11,22} + g_{12,12} - \frac{1}{2}g_{22,11},$$

where by $g_{ij,kl}$ we mean the function

$$\frac{\partial^2 g_{ij}}{\partial x^k \partial x^l}.$$

This produces the following formula for K that is appealing on the grounds that it illustrates symmetry of the metric tensor coefficients in determining K:

$$K = \frac{1}{\det(g_{ij})^2}\left(\begin{vmatrix} -\frac{1}{2}g_{11,22} + g_{12,12} - \frac{1}{2}g_{11,22} & \frac{1}{2}g_{11,1} & g_{12,1} - \frac{1}{2}g_{11,2} \\ g_{12,2} - \frac{1}{2}g_{22,1} & g_{11} & g_{12} \\ \frac{1}{2}g_{22,2} & g_{21} & g_{22} \end{vmatrix} - \begin{vmatrix} 0 & \frac{1}{2}g_{11,2} & \frac{1}{2}g_{22,1} \\ \frac{1}{2}g_{11,2} & g_{11} & g_{12} \\ \frac{1}{2}g_{22,1} & g_{21} & g_{22} \end{vmatrix} \right). \tag{7.52}$$

In the situation where one considers an orthogonal parametrization of a neighborhood of a surface, namely, when $g_{12} = 0$, Equation (7.52) takes on the particularly interesting form of

$$K = -\frac{1}{\sqrt{g_{11}g_{22}}}\left(\frac{\partial}{\partial x^1}\left(\frac{1}{\sqrt{g_{11}}}\frac{\partial\sqrt{g_{22}}}{\partial x^1} \right) + \frac{\partial}{\partial x^2}\left(\frac{1}{\sqrt{g_{22}}}\frac{\partial\sqrt{g_{11}}}{\partial x^2} \right) \right). \tag{7.53}$$

By historical habit, Equations (7.52) and (7.53) are also referred to as *Gauss's equations* and one usually refers to the collection of Equations (7.53) and (7.42) as the *Gauss-Codazzi equations*.

We now prove a theorem that we could have introduced much earlier, but it arises in part as an application of the Codazzi equations.

Definition 7.3.4. A set $S \subset \mathbb{R}^n$ is called *path-connected* if for any pair of points $p, q \in S$, there exists a continuous path (curve) $\alpha : [0,1] \to \mathbb{R}^n$, with $\alpha(0) = p$, $\alpha(1) = q$, and $\alpha([0,1]) \subset S$.

Proposition 7.3.5. *If S is a path-connected regular surface in which all its points are umbilical, then S is either contained in a plane or in a sphere.*

Proof: Let $U \subset \mathbb{R}^2$ be an open set, and let $\vec{X} : U \to \mathbb{R}^3$ be the parametrization of a neighborhood $V = \vec{X}(U)$ of S. Since all points of S are umbilical, then the eigenvalues of dn_p are equal to a value λ that a priori is a function of the coordinates (u, v) of the patch V. We first show that $\lambda(u, v)$ is a constant over U.

By Proposition 6.4.4, there always exist two linearly independent eigenvectors to dn_p, so dn_p is always diagonalizable. Thus, at any point p of S, the whole tangent plane T_pS is the eigenspace of the eigenvalue λ. Thus, in particular we have

$$\begin{aligned} \vec{N}_u &= dn_p(\vec{X}_u) = \lambda\vec{X}_u, \\ \vec{N}_v &= dn_p(\vec{X}_v) = \lambda\vec{X}_v. \end{aligned}$$

Since $\vec{N}_{uv} = \vec{N}_{vu}$, a fact that is equivalent to the Codazzi equations (see Problem 7.3.1), we have

$$\lambda_v \vec{X}_u + \lambda \vec{X}_{uv} = \lambda_u \vec{X}_v + \lambda \vec{X}_{vu}.$$

Since $\vec{X}_u$ and $\vec{X}_v$ are linearly independent, we deduce that $\lambda_u = \lambda_v = 0$, and therefore λ is a constant function.

If $\lambda = 0$, then $\vec{N}_u = \vec{N}_v = \vec{0}$, so the unit normal vector $\vec{N}$ is a constant vector $\vec{N}_0$ over the domain U. Then

$$\frac{\partial}{\partial u}(\vec{X} \cdot \vec{N}_0) = \vec{X}_u \cdot \vec{N}_0 + \vec{0} = \vec{0}$$

and similarly for $\frac{\partial}{\partial v}(\vec{X} \cdot \vec{N}_0) = \vec{0}$, which shows that $\vec{X} \cdot \vec{N}_0 = \vec{0}$, which further proves that $V = \vec{X}(U)$ lies in the plane through p perpendicular to $\vec{N}_0$.

On the other hand, if $\lambda \neq 0$, then consider the vector function

$$\vec{Y}(u,v) = \vec{X}(u,v) - \frac{1}{\lambda}\vec{N}(u,v).$$

By a similar calculation as above, we see that the function $\vec{Y}(u,v)$ is a constant vector. Then we deduce that

$$\|\vec{X}(u,v) - \vec{Y}\| = \left\|\frac{1}{\lambda}\vec{N}\right\| = \frac{1}{|\lambda|},$$

which shows that $V = \vec{X}(U)$ lies on a sphere of center $\vec{Y}$ and of radius $1/|\lambda|$.

So far, the above proof has established that any parametrization of a neighborhood V of S either lies on a sphere or lies in a plane but not that all of S necessarily lies on a sphere or in a plane. The assumption that S is path-connected extends the result to the whole surface as follows.

By Example 7.1.10, if V_1 and V_1 are two coordinate patches of S with respective coordinate systems (x^1, x^2) and $(\bar{x}^1, \bar{x}^2)$ such that $V_1 \cap V_2 \neq \emptyset$, then on $V_1 \cap V_2$ the coefficients of the Gauss map with respect to the coordinate systems are related by

$$\bar{a}^i_j = \frac{\partial \bar{x}^i}{\partial x^k} \frac{\partial x^l}{\partial \bar{x}^j} a^k_l.$$

This is tantamount to saying that the matrices for the Gauss map relative to different coordinate systems are similar matrices. Hence, if V_1 and V_2 are two overlapping coordinate patches, then the eigenvalue λ is constant over $V_1 \cup V_2$, and then all of $V_1 \cup V_2$ either lies in a plane or on a sphere.

Since S is path-connected, given any two points p and q on S, there exists a path $\alpha : [0,1] \to S$, with $\alpha(0) = p$ and $\alpha(1) = q$. From basic facts in topology, we know that $\alpha([0,1])$ is a compact set and that any open cover of a compact set has a finite subcover. Thus, given a collection of coordinate patches that cover $\alpha([0,1])$, then only a finite subcollection of these coordinate patches is necessary to cover $\alpha([0,1])$. Call this collection $\{V_1, V_2, \ldots, V_r\}$. By the reasoning in the above paragraph, we see that $V_1 \cup V_2 \cup \cdots \cup V_r$ lies either in a plane or on a sphere. Thus all points of S either lie in the same plane or lie on the same sphere. ☐

Problems

7.3.1. Show that one can obtain the Codazzi equations from the equation $\vec{N}_{12} = \vec{N}_{21}$ and by using the Gauss equations in Equation (7.29).

7.3.2. Prove that the Riemann symbols defined in Equation (7.46) form the components of a $(1,3)$-tensor.

7.3.3. Prove Equation (7.48) and the claim that supports it.

7.3.4. Suppose that $g_{12} = L_{12} = 0$ (i.e., the coordinate lines are lines of curvature), so that the principal curvatures satisfy

$$\kappa_1 = \frac{L_{11}}{g_{11}} \qquad \text{and} \qquad \kappa_2 = \frac{L_{22}}{g_{22}}.$$

Prove that the Codazzi equations are equivalent to

$$\frac{\partial \kappa_1}{\partial x^2} = \frac{g_{11,2}}{2g_{11}}(\kappa_2 - \kappa_1) \qquad \text{and} \qquad \frac{\partial \kappa_2}{\partial x^1} = \frac{g_{22,1}}{2g_{22}}(\kappa_1 - \kappa_2),$$

where by $g_{11,2}$ we mean $\frac{\partial g_{11}}{\partial x^2}$ and similarly for $g_{22,1}$.

7.3.5. Prove that the Riemann symbols R^l_{ijk} defined in Equation (7.46) are antisymmetric in the indices $\{i,j\}$. Conclude that for surfaces, R^l_{ijk} represent at most four distinct functions.

7.3.6. Prove Equation (7.53).

5- 62 3

Proposition 8.4.11. *A compact, regular, orientable surface of class C^3 with positive curvature everywhere is homeomorphic to a sphere.*

Proof: Since $K > 0$ over the whole surface S, then for the total Gaussian curvature we have

$$\iint_S K\, ds > 0.$$

By Corollary 8.4.9, this integral is $2\pi\chi(S)$. However, by the Classification Theorem of Surfaces and Equation (8.40), since $\chi(S) > 0$, we have $\chi(S) = 2$, and therefore S is homeomorphic to a sphere. □

Proposition 8.4.12. *Let S be a compact, connected, orientable, regular surface of positive Gaussian curvature. If there exist two simple, closed geodesics γ_1 and γ_2 on S then they intersect.*

Proof: By Proposition 8.4.11, S is homeomorphic to a sphere. Suppose that γ_1 and γ_2 do not intersect. Then they form the boundary of region $\mathcal{R}$ that is homeomorphic to a cylinder with boundary. It is not hard to verify by supplying $\mathcal{R}$ with a triangulation that $\chi(\mathcal{R}) = 0$. However, applying the Gauss-Bonnet Theorem to this situation, we obtain

$$\iint_{\mathcal{R}} K\, dS = 0,$$

which is a contradiction since $K > 0$. □

We now discuss applications of the Gauss-Bonnet Theorem to plane, spherical, and hyperbolic geometry and show how the theorem simultaneously generalizes many well-known theorems in these areas.

8.4.3 Plane, Spherical, and Hyperbolic Geometry

As mentioned in the introduction to this chapter, in his *Elements*, Euclid proves all his propositions through from 23 definitions and five postulates. The fifth postulate reads as follows:

> If a straight line crossing two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if extended indefinitely, meet on that side on which are the angles less than the two right angles.

Much wordier than the other four, many mathematicians over the centuries attempted to prove the fifth postulate from the others but never succeeded. Studying Euclid's *Elements*, one notices that Euclid himself uses the fifth postulate sparingly. One could speculate that Euclid did this so that, were someone to prove the fifth postulate as a consequence of the others, then the proofs of theorems would still be given in a minimal form. Indeed, many commonly known properties about plane geometry hold without reference to the fifth postulate. However, examples of two commonly known theorems that appear to rely on it are the following:

1. Given a line L and a point P not on L, through P passes exactly one line parallel to L.
2. The sum of the interior angles of a triangle is π.

In the nineteenth century, mathematicians Lobachevsky and Bolyai constructed examples of what we now call non-Euclidean geometries, in which one replaces Euclid's fifth postulate with one of two options. Given a line L and a point P not on L, through P passes (S) no parallel lines to L or (H) more than one parallel line to L. These geometries are called, respectively, *spherical geometry* and *hyperbolic geometry*. Using elementary techniques, one can study these geometries and establish many theorems, including theorems in spherical trigonometry. (See [9] and [27] for comprehensive treatment of non-Euclidean geometry using elementary techniques.) One well-known result in these geometries is that the sum of the interior angles of a triangle is greater than π in the case of spherical geometry and less than π in the case of hyperbolic geometry. Figure 8.15 gives an example of a triangle on a sphere in which each vertex has a right angle, and hence, the sum of the interior angles is $3\pi/2$.

We now apply the Gauss-Bonnet Theorem to plane, spherical, and hyperbolic geometries, beginning with plane geometry.

In plane geometry, we consider the plane to be a surface with Gaussian curvature identically 0 and curves in the plane we consider to be curves on a surface. Consider now a region $\mathcal{R}$ in the plane such that the boundary $\partial\mathcal{R}$ is a piecewise regular, simple, closed curve.

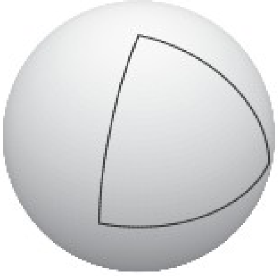


Figure 8.15. Triangle on a sphere.

It is easy to calculate that the Euler characteristic of a region that is homeomorphic to a disk is $\chi(\mathcal{R}) = 1$.

As a first case, let $\partial\mathcal{R}$ be a polygon. Since the regular arcs are straight lines, the geodesic curvature of each regular arc of $\partial\mathcal{R}$ is identically 0. Gauss-Bonnet's formula then reduces to the well-known fact that the sum of the exterior angles $\{\theta_1, \theta_2, \dots, \theta_k\}$ around a polygon is 2π. Also, since the exterior angle θ_i at any corner is $\pi - \alpha_i$, where α_i is the interior angle, we deduce that the sum of the interior angles of any polygon is

$$\sum_{i=1}^{n} \alpha_i = (n-2)\pi.$$

This statement is in fact equivalent to a theorem that occurs in every high school geometry curriculum, namely, that the sum of the interior angles of a triangle is π radians.

As a second case of the Gauss-Bonnet Theorem applied to plane geometry, suppose that $\partial\mathcal{R}$ is a regular curve. In this case, $\partial\mathcal{R}$ has no vertices and hence no exterior angles. Then the Gauss-Bonnet Theorem reduces to the formula

$$\oint_{\partial\mathcal{R}} \kappa_g \, ds = 2\pi,$$

and hence, the Gauss-Bonnet Theorem generalizes the proposition that the rotation index of a simple, closed curve is 1 (see Propositions 2.2.1 and 2.2.8).

In order to apply the results of this chapter to non-Euclidean geometry, one must clarify the use of the terms "line" and "parallel." In the geometry on a surface of class C^3, the word "line" (or straight line) means a geodesic. The word "parallel" is a little more problematic. In Problem 1.3.12, we defined a parallel curve to a given curve $\vec{\gamma}$ as a curve whose locus is always a fixed orthogonal distance r from the locus of $\vec{\gamma}$. This is true of parallel lines in the plane. However, in the sense of classical geometry, two lines are called parallel if they do not intersect.

Example 8.2.7 showed that geodesics on a sphere are great arcs of the sphere, i.e., an arc on the circle of intersection between the sphere and a plane through the center of the sphere. Therefore, any two geodesic lines intersect at at least two points: the common intersection of the sphere and the two planes supporting the geodesics. This remark justifies the definition of spherical geometry as a geometry in which there exist no parallel lines.

Consider now a triangle $\mathcal{R}$ on a sphere of radius R. By definition of a geometric triangle, $\partial\mathcal{R}$ has three vertices, and its regular arcs are geodesic curves. The Gaussian curvature of a sphere of radius R is $\frac{1}{R^2}$. In this situation, the Gauss-Bonnet Theorem gives

$$(\theta_1 + \theta_2 + \theta_3) + \frac{A}{R^2} = 2\pi, \tag{8.45}$$

where A is the surface area of $\mathcal{R}$, and θ_i are the exterior angles of the vertices. If we call $\alpha_i = \pi - \theta_i$ the interior angles of the triangle, then Equation (8.45) reduces to

$$\alpha_1 + \alpha_2 + \alpha_3 = \pi + \frac{A}{R^2}. \tag{8.46}$$

This shows that in a spherical triangle, the excess sum of the angles, i.e., $\alpha_1 + \alpha_2 + \alpha_3 - \pi$, is 4π times the ratio of the surface area of the triangle to the surface area of the whole sphere. As an example, the spherical triangle in Figure 8.15 has an excess of $\pi/2$ and covers $1/8$ of the sphere.

We propose to study (geodesic) circles on a sphere of radius R. Recall that a circle on a sphere is the set of points that are at a fixed distance r from a point, where distance here means geodesic

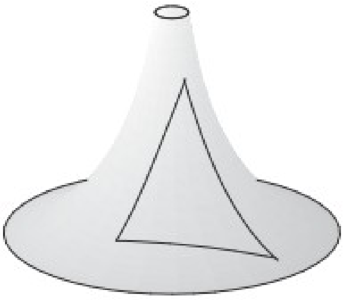

Figure 8.16. Hyperbolic triangle.

distance. Call $\mathcal{D}$ the closed disk inside this circle. Using the parametric equations for the sphere,

$$\vec{X}(u,v) = (R\cos u \sin v, R\sin u \sin v, R\cos v),$$

a circle of radius r around the north pole $(0,0,R)$ is given by $\vec{\gamma}(t) = \vec{X}(t, v_0)$, where $r = Rv_0$. It is not hard to tell by symmetry that the geodesic curvature κ_g of a circle on a sphere is a constant. The Gauss-Bonnet Theorem then gives

$$\kappa_g(\text{perimeter of } \partial\mathcal{D}) + \frac{1}{R^2}(\text{surface area of } \mathcal{D}) = 2\pi. \tag{8.47}$$

Using the surface area formula for a surface of revolution from single-variable calculus, it is possible to prove that the area of $\mathcal{D}$ is

$$\text{surface area of } \mathcal{D} = 2\pi R^2(1-\cos v_0) = 2\pi R^2\left(1-\cos\left(\frac{r}{R}\right)\right).$$

It is not hard to show that the perimeter of $\mathcal{D}$ is

$$\text{perimeter of } \mathcal{D} = 2\pi R \sin v_0 = 2\pi R \sin\left(\frac{r}{R}\right).$$

Consequently, the Gauss-Bonnet Theorem gives the curvature of a circle on a sphere as

$$\kappa_g = \frac{1}{R}\cot\left(\frac{r}{R}\right).$$

In contrast to spherical geometry, hyperbolic geometry is the geometry of a surface with constant negative Gaussian curvature. Example 6.5.5 presented the pseudosphere as a surface with $K = -1$

everywhere. In this particular case, using the Gauss-Bonnet Theorem, it is easy to calculate that the sum of the interior angles of a triangle is

$$\alpha_1 + \alpha_2 + \alpha_3 = \pi - A,$$

where A is the area of the triangle. (See Figure 8.16 for an example. Note that the regular arcs are indeed geodesic segments.) Interestingly enough, this formula for the sum of the interior angles of a hyperbolic triangle puts an upper bound of π for the possible area of a triangle on the pseudosphere with $K = -1$.

Problems

8.4.1. Provide all the details that establish Equation (8.36).

8.4.2. Provide the details for the proof of Lemma 8.4.6.

8.4.3. Calculate the surface area of a disk on a sphere using the surface area formula for a surface of revolution. Calculate directly the geodesic curvature function of a circle on a sphere. [Hint: See the paragraph around Equation (8.47).]

8.4.4. Verify directly the Gauss-Bonnet Theorem for the rectangular region $\mathcal{R}$ on a torus specified by $u_1 \leq u \leq u_2$ and $v_1 \leq v \leq v_2$, where the u-coordinate lines are the parallels and the v-coordinate lines are the meridians of the torus, as a surface of revolution.

8.4.5. Let S be a regular, orientable, compact surface with positive Gaussian curvature. Prove that the surface area of S is less than $4\pi/K_{\min}$, where $K_{\min} > 0$ is the minimum Gaussian curvature.

8.4.6. Let S be a regular, orientable surface of class C^3 in $\mathbb{R}^3$ that is homeomorphic to the sphere. Let γ be a simple closed geodesic in S. The curve γ separates S into two regions A and B that share γ as their boundary. Let $n : S \to \mathbb{S}^2$ be the Gauss map induced from a given orientation of S. Prove that $n(A)$ and $n(B)$ have the same area.

8.4.7. Let S be an orientable surface with Gaussian curvature $K \geq 0$, and let $p \in S$.

(a) Let γ_1 and γ_2 be two geodesics that intersect at p. Prove that γ_1 and γ_2 do not intersect at another point q in such a way that γ_1 and γ_2 form the boundary of a simple region $\mathcal{R}$.

(b) Prove also that a geodesic on S cannot intersect itself in such a way as to enclose a simple region.

8.4.8. *Jacobi's Theorem.* Let $\vec{\alpha} : I \to \mathbb{R}^3$ be a closed, regular, parametrized curve. Suppose also that $\vec{\alpha}(t)$ has a curvature function $\kappa(t)$ that is never 0. Suppose also that the principal normal indicatrix, i.e., the curve $\vec{P} : I \to \mathbb{S}^2$, is simple, that is, that it cuts the sphere into only two regions. By viewing $\vec{P}(I)$ as a curve on the sphere $\mathbb{S}^2$, use the Gauss-Bonnet Theorem to prove that $\vec{P}(I)$ separates the sphere into two regions of equal area.

8.5 Intrinsic Geometry

We remind the reader that an intrinsic property of a regular surface or a regular curve on a surface is a property that depends only on the coefficients of the metric tensor and the coordinates of a point or coordinate functions of a curve. Intrinsic geometry is the subset of differential geometry where one restricts one's attention to intrinsic properties.

In Section 6.1, we saw that the arc length of a curve on a surface, the area of a region on the surface, and the angle between two intersecting curves are all intrinsic properties of surfaces. As a consequence, a surface integral and an integral along a path (parametrized by arc length) of functions given in terms of the coordinates are intrinsic quantities. In contrast, the normal vector to a surface at a point and even the second fundamental form are not intrinsic. On the other hand, in Section 7.2 we saw that the Christoffel symbols Γ^i_{jk} are intrinsic quantities, and the Theorema Egregium (Theorem 7.3.2) shows that the Gaussian curvature is also an intrinsic property of the surface.

As far as curves on surfaces, Equation (8.7) shows the geodesic curvature to be an intrinsic property. Furthermore, since the differential equations for geodesics involve only the Christoffel symbols and the coordinate functions of the curve, geodesics are objects in intrinsic geometry. However, the functional dependence of the normal curvature and the geodesic torsion on the unit normal vector, as given in Equation (8.11), indicates that these quantities are not intrinsic. Since the Gauss-Bonnet formula on one side only involves κ_g and K, one may say it is a theorem in intrinsic geometry.

The value of narrowing one's focus to intrinsic geometry is that, in this context, one does not need a specific parametrization (coordinate patch) of a surface to calculate the quantities or determine curves of interest. In Chapters 6, 7, and 8, we have almost exclusively considered regular surfaces in $\mathbb{R}^3$. However, if $\vec{X} : U \to \mathbb{R}^n$, where U is an open subset of $\mathbb{R}^2$, though it is impossible to define *the* unit normal vector (even up to sign), it is still possible to calculate

$$g_{ij} = \vec{X}_i \cdot \vec{X}_j.$$

Therefore, given the metric tensor, the dimension of the ambient Euclidean space of the surface or even how the surface sits in the ambient space is irrelevant. One simply refers to the coordinates in a given coordinate patch and the associated metric tensor for all calculations.

The concept of a differentiable manifold, the next step in the generalization of regular surfaces, avoids any reference to an ambient space. However, without an ambient space, one cannot really do geometry on a differentiable manifold (measure lengths, angles, volumes, curvatures, etc.) without a metric tensor. A manifold equipped with a metric tensor is called a *Riemannian manifold*. Chapters 3 through 5 in [22] study differentiable and Riemannian manifolds.

Example 8.5.1 (Flat Torus). The topological definition of a torus is a topological space that is homeomorphic to $\mathbb{S}^1 \times \mathbb{S}^1$, where $\mathbb{S}^1$ is a circle.

Throughout this book, we have used the following parametrization $\vec{X} : [0, 2\pi]^2 \to \mathbb{R}^3$ of the torus as a surface in $\mathbb{R}^3$:

$$\vec{X}(u, v) = ((R + r\cos v)\cos u, (R + r\cos v)\sin u, r\sin v).$$

The locus of this parametrization is the usual doughnut shape that is the surface of revolution of circle of radius r with center a distance R from the axis of revolution. As long as $0 < r < R$, the image of this parametrization is indeed a topological torus. In the context of differential geometry it is this shape that one calls a torus. As the exercises in Chapter 6 showed, this parametrization has a nontrivial metric tensor.

Problem 6.1.14 introduced the parametrization $\vec{X} : [0, 2\pi]^2 \to \mathbb{R}^4$ given by the functions

$$\vec{X}(u, v) = (\cos u, \sin u, \cos v, \sin v).$$

This parametrization explicitly traces out $\mathbb{S}^1 \times \mathbb{S}^1$. It is easy to see that the metric tensor (g_{ij}) associated to this parametrization is the identity matrix everywhere. This justifies the name of flat torus for this shape. In some intuitive sense, the reason why it is possible for a flat torus to exist is that, like the right circular cylinder in $\mathbb{R}^3$ that has $g_{ij} = \delta^i_j$, there is "enough room" in $\mathbb{R}^4$ to have a torus that has a metric tensor that is everywhere the identity matrix.

Example 8.5.2 (Poincaré Half-Plane). We consider the upper half-plane $H = \{(x, y) \in \mathbb{R}^2 \mid y > 0\}$ with the metric tensor

$$(g_{ij}) = \begin{pmatrix} y^{-2} & 0 \\ 0 & y^{-2} \end{pmatrix}.$$

Using the physics-style line element notation, the metric is written as $ds^2 = \frac{1}{y^2}(dx^2 + dy^2)$. The area element in H with this metric is

$$dS = \sqrt{\det(g)}\, dA = \frac{1}{y^2}\, dx\, dy.$$

So, for example, the surface integral of a function $f : H \to \mathbb{R}$ over a region $\mathcal{R}$ is

$$\iint_{\mathcal{R}} f\, dS = \iint_{\mathcal{R}} \frac{f(x, y)}{y^2}\, dx\, dy.$$

The area of a rectangle $\mathcal{R} = \{(x, y) \in H \mid x_1 \leq x \leq x_2,\ y_1 \leq y \leq y_2\}$ is

$$A = \int_{y_1}^{y_2} \int_{x_1}^{x_2} \frac{1}{y^2}\, dx\, dy = (x_2 - x_1)\left(\frac{1}{y_1} - \frac{1}{y_2}\right).$$

The Poincaré half-plane has many interesting properties that are explored in the exercises. One remarkable property is that the geodesic lines in H with the Poincaré metric are either vertical lines or half-circles with center on the x-axis.

Fig. 5.4 The non-planarity of $L(K_{1,1,3})$

Proof We show that (1) $\Longrightarrow$ (3), (3) $\Longrightarrow$ (2), and (2) $\Longrightarrow$ (1).
(1) $\Longrightarrow$ (3): We first show that the line graph of each of the four given graphs is nonplanar.

(a) $L(K_{3,3})$: Since $K_{3,3}$ is itself nonplanar, this follows from the lemma.
(b) $L(K_{1,5})$: This line graph is nonplanar since it is K_5 itself.
(c) $L(K_{1,1,3})$: Consider the edge-labeling of $K_{1,1,3}$ in Fig. 5.4. This figure also shows its line graph with its vertices labeled and three of its edges (df, dg, and fg) colored blue. It is easy to verify that the subgraph with only the black edges is homeomorphic to K_5. Hence the line graph of $K_{1,1,3}$ is nonplanar.
(d) $L(K_1 * P_4)$: Similarly, consider the edge-labeling of $K_1 * P_4$ in Fig. 5.5 along with its line graph. Once again the black edges constitute a homeomorph of K_5, so $L(K_1 * P_4)$ is nonplanar.

$$\int_0^1 x^p \, dx = \frac{1}{p+1}$$

4 % - 4 9+ -)

$$\frac{0^p + 1^p + 2^p + \cdots + n^p}{n^p + n^p + n^p + \cdots + n^p} \to \frac{1}{p+1} \quad \text{as} \quad n \to \infty.$$

9.4 The *Arithmetica Infinitorum* of Wallis

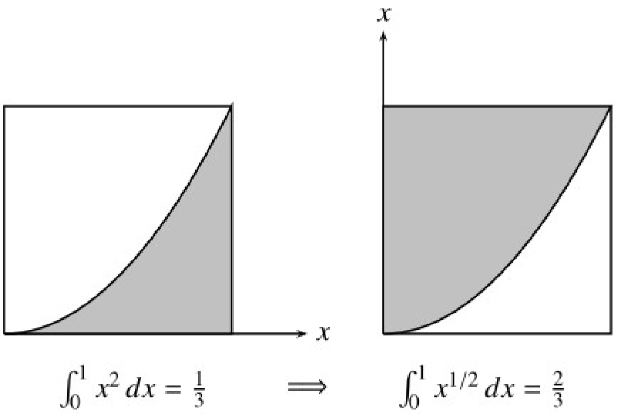
Wallis's efforts to arithmetize geometry were noted in Section 7.6. In his *Arithmetica Infinitorum*, Wallis (1655a) made a similar attempt to arithmetize the theory of areas and volumes of curved figures. Some of his results were, understandably, equivalent to results already known. For example, he gave a proof that

$$\int_0^1 x^p\,dx = \frac{1}{p+1}$$

for positive integers p by showing that

$$\frac{0^p + 1^p + 2^p + \cdots + n^p}{n^p + n^p + n^p + \cdots + n^p} \to \frac{1}{p+1} \quad \text{as} \quad n \to \infty.$$

However, he made a new approach to fractional powers, finding $\int_0^1 x^{m/n}\,dx$ directly rather than by consideration of the curve $y^n = x^m$, as Fermat had done. He first found $\int_0^1 x^{1/2}\,dx$, $\int_0^1 x^{1/3}\,dx$, ... by considering the areas complementary to those under $y = x^2, y = x^3, \ldots$ (Figure 9.2), then guessed the results for other fractional powers by analogy with those already obtained.



x
x
$\int_0^1 x^2\,dx = \frac{1}{3}$
$\Longrightarrow$
$\int_0^1 x^{1/2}\,dx = \frac{2}{3}$

Figure 9.2: Areas used by Wallis

Like other early contributors to calculus, Wallis was ambivalent about quantities that tended to zero, treating them as nonzero one minute and zero the next. For this he received a ferocious blast from his arch-enemy Thomas Hobbes: "Your scurvy book of *Arithmetica infinitorum*; where your indivisibles have nothing to do, but as they are supposed to have quantity, that is to say, to be *divisibles*" (Hobbes (1656), p. 301). Quite apart from this fault, which is easily remedied by limit arguments, the reasoning of Wallis is extremely incomplete by today's standards. Observing a pattern in formulas for $p = 1, 2, 3$, for example, he will immediately claim a formula for all positive integers p "by induction" and for fractional p "by interpolation." His boldness reached new heights toward the end of the *Arithmetica infinitorum* in deriving his famous infinite product formula,

$$\frac{\pi}{4} = \frac{2}{3} \cdot \frac{4}{3} \cdot \frac{4}{5} \cdot \frac{6}{5} \cdot \frac{6}{7} \cdot \cdots.$$

An exposition of his reasoning may be found in Edwards (1979), pp. 171–176, where it is described as "one of the more audacious investigations by analogy and intuition that has ever yielded a correct result."

However, we must bear in mind that Wallis was offering primarily a method of discovery, and what a discovery he made! His infinite product for π was not the first ever given, since Viète (1593) had discovered

$$\begin{aligned}\frac{2}{\pi} &= \cos\frac{\pi}{4}\cos\frac{\pi}{8}\cos\frac{\pi}{16}\cdots\\ &= \sqrt{\frac{1}{2}} \cdot \sqrt{\frac{1}{2}\left(1 + \sqrt{\frac{1}{2}}\right)} \cdot \sqrt{\frac{1}{2}\left[1 + \sqrt{\frac{1}{2}\left(1 + \sqrt{\frac{1}{2}}\right)}\right]} \cdot \cdots.\end{aligned}$$

However, the formula of Viète is based on a clever but simple trick (see exercises), whereas that of Wallis is of deeper significance. By relating π to the integers through a sequence of rational operations, Wallis uncovered a sequence of fractions, obtained by terminating the product at the nth factor, that he called "hypergeometric." Similar sequences were later found to occur as coefficients in series expansions of many functions, which led to a broad class of functions being called "hypergeometric" by Gauss. Also, Wallis's product was closely related to two other beautiful formulas for π based on sequences of rational operations:

$$\frac{4}{\pi} = 1 + \cfrac{1^2}{2 + \cfrac{3^2}{2 + \cfrac{5^2}{2 + \cfrac{7^2}{2 + \cdots}}}}$$

and

$$\frac{\pi}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \cdots .$$

The continued fraction was obtained by Brouncker from Wallis's product and also published in Wallis (1655b). The series is a special case of the series

$$\tan^{-1} x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \cdots$$

discovered by the Indian mathematician Mādhava in the 15th century (see Section 10.1) and rediscovered by Newton, Gregory, and Leibniz. Euler (1748a), p. 311, gave a direct transformation of the series for $\pi/4$ into Brouncker's continued fraction. Besides setting off this spectacular chain reaction, Wallis's method of "interpolation" had important consequences in the work of Newton, who used it to discover the general binomial theorem (Section 10.2).

EXERCISES

9.4.1 Use the identity $\sin x = 2\sin(x/2)\cos(x/2)$ to show that

$$\frac{\sin x}{2^n \sin(x/2^n)} = \cos\frac{x}{2}\cos\frac{x}{2^2}\cdots\cos\frac{x}{2^n},$$

whence

$$\frac{\sin x}{x} = \cos\frac{x}{2}\cos\frac{x}{2^2}\cos\frac{x}{2^3}\cdots .$$

9.4.2 Deduce Viète's product by substituting $x = \pi/2$.

The equation relating the series for $\pi/4$ to the continued fraction for $4/\pi$, namely

$$1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \cdots = \cfrac{1}{1 + \cfrac{1^2}{2 + \cfrac{3^2}{2 + \cfrac{5^2}{2 + \cfrac{7^2}{2 + \cdots}}}}}$$

follows immediately from a more general equation

$$\frac{1}{A} - \frac{1}{B} + \frac{1}{C} - \frac{1}{D} + \cdots = \cfrac{1}{A + \cfrac{A^2}{B - A + \cfrac{B^2}{C - B + \cfrac{C^2}{D - C + \cdots}}}}$$

where x_3 is none other than the x-coordinate of the third point on

$$y^2 = 4x^3 - g_2x - g_3$$

of the straight line through (x_1, y_1) and (x_2, y_2) (see Section 11.6). Now that we know, from Section 12.2, that this curve is parameterized by $x = \wp(u)$, $y = \wp'(u)$, defined by inverting the integral, some connection between the geometry of the curve and the addition theorem is understandable. But the stunning simplicity of the relationship seems to demand a deeper explanation. This lies in the realm of complex numbers, which we shall enter briefly in the next section and more thoroughly in Sections 16.4 and 16.5.

EXERCISES

12.5.1 Show that the substitution $t = 1/u$ transforms

$$\frac{dt}{\sqrt{(t-a)(t-b)(t-c)}} \quad \text{into} \quad \frac{-du}{\sqrt{u(1-ua)(1-ub)(1-uc)}}.$$

Conversely, we can transform quartic polynomials under the square root sign to cubics, even in cases where the quartic is not of the form obtained in Exercise 12.5.1.

12.5.2 Transform

$$\frac{dt}{\sqrt{1-t^4}} \quad \text{into} \quad \frac{du}{\sqrt{\text{cubic polynomial in } u}}$$

by making a suitable substitution for t.

12.6 Elliptic Functions

The idea of inverting elliptic integrals to obtain elliptic functions is due to Gauss, Abel, and Jacobi. Gauss had the idea in the late 1790s but did not publish it; Abel had the idea in 1823 and published it in 1827, independently of Gauss. Jacobi's independence is not quite so clear. He seems to have been approaching the idea of inversion in 1827, but he was stung into action only by the appearance of Abel's paper. At any rate, his ideas subsequently developed at an explosive rate, and he published the first book on elliptic functions, the *Fundamenta nova theoriae functionum ellipticarum*, two years later (Jacobi (1829)).

Gauss first considered inverting an elliptic integral in 1796, in the case of $\int dt/\sqrt{1-t^3}$. The following year he inverted the lemniscatic integral and made better progress. Defining the "lemniscatic sine function" $x = sl(u)$ by

$$u = \int_0^x \frac{dt}{\sqrt{1-t^4}},$$

he found that this function is periodic, like the sine, with period

$$2\varpi = 4\int_0^1 \frac{dt}{\sqrt{1-t^4}}.$$

Gauss also noticed that $sl(u)$ invites complex arguments, since it follows from $i^2 = -1$ that

$$\frac{d(it)}{\sqrt{1-(it)^4}} = i\frac{dt}{\sqrt{1-t^4}};$$

hence $sl(iu) = isl(u)$ and the lemniscatic sine has a second period $2i\varpi$. Thus Gauss discovered *double periodicity*, one of the key properties of the elliptic functions, though at first he did not realize its universality. The scope and importance of elliptic functions hit him on May 30, 1799, when he discovered an extraordinary numerical coincidence. His diary entry of that day reads:

> We have established that the arithmetic-geometric mean between 1 and $\sqrt{2}$ is π/ϖ to 11 places; the demonstration of this fact will surely open up an entirely new field of analysis.

Gauss had been fascinated by the arithmetic–geometric mean since 1791, when he was 14. The arithmetic–geometric mean of two positive numbers a and b is the common limit, $\mathrm{agM}(a, b)$, of the two sequences $\{a_n\}$ and $\{b_n\}$ defined by

$$\begin{aligned} a_0 &= a, & b_0 &= b, \\ a_{n+1} &= \tfrac{a_n+b_n}{2}, & b_{n+1} &= \sqrt{a_n b_n}. \end{aligned}$$

For more information on the theory and history of the agM function, see Cox (1984).

It is indeed true that $\mathrm{agM}(1, \sqrt{2}) = \pi/\varpi$, as Gauss soon proved, and the "entirely new field of analysis" he created from the merger of these ideas was extraordinarily rich. It encompassed elliptic functions in general, the theta functions later rediscovered by Jacobi, and the modular functions later rediscovered by Klein. The theory was not clearly improved until the

1850s, when Riemann showed that double periodicity becomes obvious when elliptic integrals are placed in a suitable geometric setting.

Unfortunately, Gauss released virtually none of his results on elliptic functions. Apart from publishing an expression for $\mathrm{agM}(a, b)$ as an elliptic integral (Gauss (1818)), he did nothing until Abel's results appeared in 1827—then promptly claimed them as his own. He wrote to Bessel (Gauss (1828)):

> I shall most likely not soon prepare my investigations on the transcendental functions which I have had for many years—since 1798. …Herr Abel has now, as I see, anticipated me and relieved me of the burden in regard to one third of these matters.

It was disingenuous of Gauss to claim he had more results than Abel, because Abel also had results unknown to Gauss. True, Gauss had priority on the key ideas of inversion and double periodicity, but priority isn't everything, as Gauss himself perhaps knew. His own cherished discovery of the relation between agM and elliptic integrals had not only been found earlier, but even published by Lagrange (1785).

EXERCISES

The following exercises show how the lemniscatic sine and its derivative are quite analogous to the ordinary sine and its derivative, the cosine.

12.6.1 Show that $sl'(u) = \sqrt{1 - sl^4(u)}$.

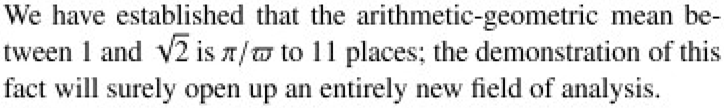
12.6.2 Deduce from the Euler addition theorem (Section 12.4) that

$$sl(u+v) = \frac{sl(u)sl'(v) + sl(v)sl'(u)}{1 + sl^2(u)sl^2(v)}.$$

12.7 A Postscript on the Lemniscate

The duplication of the arc of the lemniscate had some interesting consequences for the lemniscate itself. Fagnano showed, by similar arguments, that a quadrant of the lemniscate can be divided into two, three, or five equal arcs by ruler and compass (see Ayoub (1984)). This raised a question: for which n can the lemniscate be divided into n equal parts by ruler and compass? Recall from Section 2.3 that the corresponding question for the circle had been answered by Gauss (1801), Art. 366. As mentioned

E 4)



> We have established that the arithmetic-geometric mean between 1 and $\sqrt{2}$ is π/ϖ to 11 places; the demonstration of this fact will surely open up an entirely new field of analysis.

intermediate value theorem and extreme value theorem. This completed not only the second proof of Gauss but also the proof of d'Alembert, as we shall see in the next section.

EXERCISES

Complex roots of an equation with real coefficients occur in conjugate pairs because of the fundamental properties of conjugates.

14.6.1 Show directly from the definition $\overline{u + iv} = u - iv$ that

$$\overline{z_1 + z_2} = \overline{z_1} + \overline{z_2} \quad \text{and} \quad \overline{z_1 \cdot z_2} = \overline{z_1} \cdot \overline{z_2}$$

for any complex numbers z_1, z_2.

14.6.2 Deduce from Exercise 14.6.1 that $p(\overline{z}) = \overline{p(z)}$ for any polynomial $p(z)$ with real coefficients, and hence that the complex roots of $p(z) = 0$ occur in conjugate pairs.

14.7 The Proofs of d'Alembert and Gauss

The key to d'Alembert's proof is a proposition now known as *d'Alembert's lemma*: if $p(z)$ is a nonconstant polynomial function and $p(z_0) \neq 0$, then any neighborhood of z_0 contains a point z_1 such that $|p(z_1)| < |p(z_0)|$.

The proof of this lemma offered by d'Alembert depended on solving the equation $w = p(z)$ for z as a fractional power series in w. As mentioned in Section 9.5, such a solution was claimed by Newton (1671), but it was made clear and rigorous only by Puiseux (1850). Thus d'Alembert's argument did not stand on solid ground, and in any case it was unnecessarily complicated.

A simple elementary proof of d'Alembert's lemma was given by Argand (1806). Argand was one of the co-discoverers of the geometric representation of complex numbers (probably the first was Wessel (1797), but his work remained almost unknown for 100 years), and he offered the following proof as an illustration of the effectiveness of the representation.

The value of $p(z_0) = x_0 + iy_0$ is interpreted as the point (x_0, y_0) in the plane, so that $|p(z_0)|$ is the distance of (x_0, y_0) from the origin. We wish to find a Δz such that $p(z_0 + \Delta z)$ is nearer to the origin than $p(z_0)$. If

$$p(z) = a_0 z^n + a_1 z^{n-1} + \cdots + a_n,$$

then

$$\begin{aligned} p(z_0+\Delta z) &= a_0(z_0+\Delta z)^n + a_1(z_0+\Delta z)^{n-1} + \cdots + a_n \\ &= a_0 z_0^n + a_1 z_0^{n-1} + \cdots + a_n + A_1\Delta z + A_2(\Delta z)^2 + \cdots + A_n(\Delta z)^n \\ &\quad \text{for some constants } A_i \text{ depending on } z_0, \text{ not all zero,} \\ &\quad \text{because } p \text{ is not constant} \\ &= p(z_0) + A\Delta z + \varepsilon, \end{aligned}$$

where $A = A_i(\Delta z)^i$ contains the first nonzero A_i and $|\varepsilon|$ is small compared with $|A\Delta z|$ when $|\Delta z|$ is small (because ε contains higher powers of Δz). It is then clear (Figure 14.5) that by choosing the direction of Δz so that $A\Delta z$ is opposite in direction to $p(z_0)$, we get $|p(z_0+\Delta z)| < |p(z_0)|$. This completes the proof of d'Alembert's lemma.

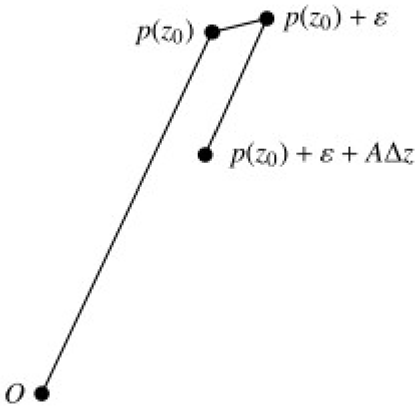

Figure 14.5: Construction for d'Alembert's lemma

To complete the proof of the fundamental theorem of algebra, take an arbitrary polynomial p and consider the continuous function $|p(z)|$. Since $p(z) \approx a_0 z^n$ for $|z|$ large, $|p(z)|$ increases with $|z|$ outside a sufficiently large circle $|z| = R$. We now get a z for which $|p(z)| = 0$ from the extreme value theorem of Weierstrass (1874); a continuous function on a closed bounded set assumes maximum and minimum values. By this theorem, $|p(z)|$ takes a minimum value for $|z| \le R$. The minimum is ≥ 0 by definition, and if it is > 0 we get a contradiction by d'Alembert's lemma: either a point z with $|z| \le R$ where $|p(z)|$ takes a value less than its minimum or a point z with $|z| > R$ where $|p(z)|$ is less than its values on $|z| = R$. Thus there is a point z where $|p(z)| = 0$ and hence $p(z) = 0$.

The proof of Gauss also used the fact that $p(z)$ behaves like its highest-degree term a_0z^n for $|z|$ large and likewise relied on a continuity argument to show that $p(z) = 0$ inside some circle $|z| = R$. Gauss considered the real and imaginary parts of $p(z)$, $\mathrm{Re}[p(z)]$ and $\mathrm{Im}[p(z)]$, and investigated the curves

$$\mathrm{Re}[p(z)] = 0 \qquad \text{and} \qquad \mathrm{Im}[p(z)] = 0.$$

(These are easily seen to be algebraic curves $p_1(x, y) = 0$ and $p_2(x, y) = 0$ by expanding the powers $z^k = (x + iy)^k$ and collecting real and imaginary terms.) His aim was to find a point where these curves meet, because at such a point

$$0 = \mathrm{Re}[p(z)] = \mathrm{Im}[p(z)] = p(z).$$

For $|z|$ large, the curves are close to the curves $\mathrm{Re}(a_0z^n)$ and $\mathrm{Im}(a_0z^n) = 0$, which are families of straight lines through the origin. Moreover, the lines where $\mathrm{Re}(a_0z^n) = 0$ *alternate* with those where $\mathrm{Im}(a_0z^n) = 0$ as one makes a circuit around the origin. For example, Figure 14.6 shows $\mathrm{Re}(z^2) = 0$ and $\mathrm{Im}(z^2) = 0$ as alternate solid and dashed lines. It follows that the curves $\mathrm{Re}[p(z)] = 0$ and $\mathrm{Im}[p(z)] = 0$ meet a sufficiently large circle $|z| = R$ *alternately*. Up to this point the argument is comparable to d'Alembert's lemma, and it can be made just as rigorous.

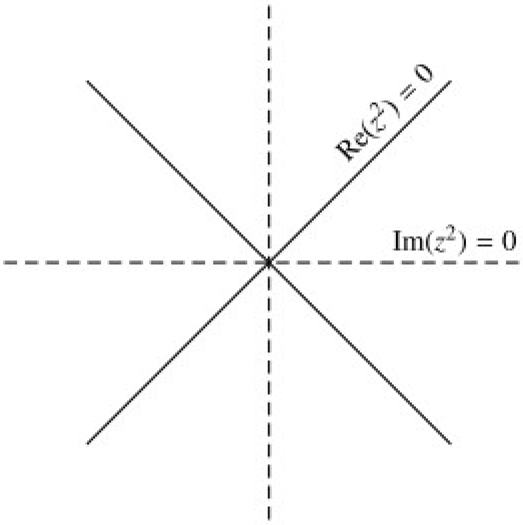

Figure 14.6: Lines for the Gauss proof

To complete this proof we have to show that the curves meet inside the circle, and this is the step Gauss thought nobody could doubt. He assumed that the separate pieces of the algebraic curve $\mathrm{Re}[p(z)] = 0$ outside the circle $|z| = R$ would join inside the circle, as would the separate pieces of $\mathrm{Im}[p(z)] = 0$. Then, since the pieces of $\mathrm{Re}[p(z)] = 0$ alternate with those of $\mathrm{Im}[p(z)]$ on $|z| = R$, it would be "patently absurd" for their connecting pieces inside the circle not to meet. One has only to visualize a situation like that seen in Figure 14.7 to feel sure that Gauss was right. However, the existence of the connecting pieces is extremely hard to prove (and proving that they meet is not trivial either, being at least as hard as the intermediate value theorem). The first proof was given by Ostrowski (1920).

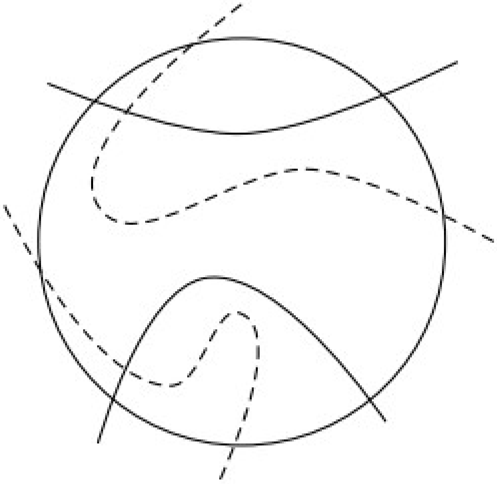

Figure 14.7: Curves for the Gauss proof

From our present perspective, d'Alembert's route to the fundamental theorem of algebra seems basically easy because it proceeds through general properties of continuous functions. The route of Gauss, although appearing equally easy from a distance, goes through the still-unfamiliar territory of real algebraic curves. The intersections of real algebraic curves are harder to understand than the intersections of complex algebraic curves, and in retrospect they are harder to understand than the fundamental theorem of algebra. Indeed, as we shall see in the next chapter, the fundamental theorem gives us Bézout's theorem, which in turn settles the problem of counting the intersections of complex algebraic curves.

EXERCISES

The expression in d'Alembert's lemma for $p(z_0+\Delta z)$ is an instance of *Taylor's series*, previously discussed in Section 10.2. When the function is a polynomial p, as here, its Taylor series is finite because p has only finitely many nonzero derivatives.

14.7.1 Show that $A_1 = na_0z_0^{n-1} + (n-1)a_1z_0^{n-2} + \cdots + a_{n-1}$ and that the latter expression is $p'(z_0)$.

14.7.2 Show that $A_2 = \frac{n(n-1)}{2}a_0z_0^{n-2} + \frac{(n-1)(n-2)}{2}a_1z_0^{n-3} + \cdots + a_{n-2}$ and that the latter expression is $p''(z_0)/2$.

14.7.3 Using the binomial theorem, show that $A_k = p^{(k)}(z_0)/k!$, and hence that

$$p(z_0 + \Delta z) = a_0z_0^n + a_1z_0^{n-1} + \cdots + a_n + A_1\Delta z + A_2(\Delta z)^2 + \cdots + A_n(\Delta z)^n$$

is an instance of the Taylor series formula.

14.8 Biographical Notes: d'Alembert

Jean le Rond d'Alembert (Figure 14.8) was born in Paris in 1717 and died there in 1783. He was the illegitimate son of the Chevalier Destouches-Canon, a cavalry officer, and salon hostess Madame de Tencin. His mother abandoned him at birth near the church of St. Jean-le-Rond in the cloisters of Notre Dame, and so he was christened Jean le Rond, following the custom for foundlings. He was subsequently located by his father, who found a home for him with a glazier named Rousseau and his wife. The name d'Alembert came later, for reasons that are unclear.

The Rousseaus must have been devoted foster parents, for d'Alembert lived with them until 1765. He received an annuity from his father, who also arranged for him to be educated at the Jansenist Collège de Quatre-Nations in Paris. There he received a good grounding in mathematics and developed a permanent distaste for theology. After brief studies in law and medicine he turned to mathematics in 1739.

In that year he began sending communications to the Académie des Sciences, and his ambition and talent rapidly carried him to fame. He became a member of the Académie in 1741 and published his best-known work, the *Traité de dynamique*, in 1743. Having struggled to the top from humble beginnings, d'Alembert did not want to lose his position. Once in the Académie, his struggle was to stay ahead of his rivals. Whether by accident or inborn competitiveness, d'Alembert always seemed to be working on the same problems as other top mathematicians—initially Clairaut, 5- <T2 /3 / # 4 ; J % O

) 4 8 $8

$p \leq mn$ in the single variable x/y. But then

$$\begin{aligned} r_{mn}(x, y) &= y^{mn-p} \prod_{i=1}^{p} (b_i x - a_i y) \\ &= \prod_{i=1}^{mn} (b_i x - a_i y) \end{aligned}$$

since each factor y in front (if any) is trivially of the form $b_i x - a_i y$.

It follows that the equation $r_{mn}(x, y) = 0$ has mn solutions, and hence there are mn intersections of C_m and C_n, counting multiplicities.

Exercises

15.1.1 Show that $y = \varepsilon x$ meets $y = x^n$ in n distinct points when $\varepsilon \neq 0$, and list them (for example, with the help of de Moivre's theorem).

If a curve K has a double point at O, then a line $y = tx$ may have double contact with K at O even though nearby lines $y = (t + \varepsilon)x$ do not meet K at nearby points other than O. In this case the double contact may be explained as contact with the two branches of the curve at O.

15.1.2 Consider the lines $y = tx$ through the double point O of $y^2 = x^2(x + 1)$. Show that each such line has double contact with the curve at O, except when $t = \pm 1$. How do you account for the multiplicities when $t = \pm 1$?

15.1.3 Show that $y = tx$ also has double contact with $y^2 = x^3$ at its cusp point O. Try to explain this by viewing $y^2 = x^3$ as the result of "shrinking the loop" of $y^2 = x^2(x + \varepsilon)$ (letting $\varepsilon \to 0$).

15.1.4 Show that the line $y = tx$ has double contact at O with the lemniscate $(x^2 + y^2)^2 = x^2 - y^2$ except for two values of t, for which it has quadruple contact.

15.1.5 Explain the multiplicities found in Exercise 15.1.4 with the help of the known shape of the lemniscate (Figure 12.1).

15.2 The Complex Projective Line

We saw in Section 8.5 that adding a point at infinity to the real line $\mathbb{R}$ in $\mathbb{R} \times \mathbb{R}$ forms a closed curve that is qualitatively like a circle. Indeed, a real projective line in the sphere model of the real projective plane $\mathbb{RP}^2$ has much the same geometric properties as a great circle on a sphere, after one allows for the fact that antipodal points on the sphere are the same point on

$\mathbb{RP}^2$. The situation with the complex "line" $\mathbb{C}$ is similar but more difficult to visualize. $\mathbb{C}$ is already two-dimensional, as we saw in Gauss's proof of the fundamental theorem of algebra; hence the complex "plane" $\mathbb{C} \times \mathbb{C}$ is four-dimensional and virtually impossible to visualize.

To avoid an excursion into four-dimensional space, we first revise our approach to the real projective line. In Section 8.5 we considered ordinary lines L, in a horizontal plane not passing through the origin, and extended each to a projective line whose "points" are the lines through the origin O, in the plane through O and L. The nonhorizontal lines in this family correspond to points of L, and the horizontal line in the family to the point at infinity of L. We now use this construction again to demonstrate directly the qualitative, or more precisely *topological*, equivalence between a projective line and a circle (Figure 15.3).

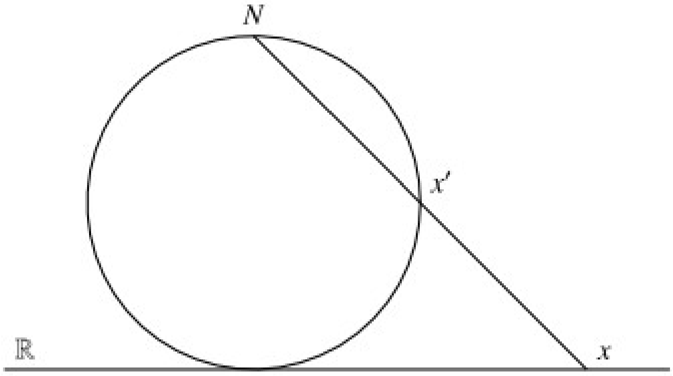

Figure 15.3: The real projective line

The origin N is taken to be the top point of a circle that, at its bottom point, touches our line $L = \mathbb{R}$. There is a continuous one-to-one correspondence between lines through N and points of the circle. Each nonhorizontal line corresponds to its intersection $x' \neq N$ with the circle, while the horizontal line corresponds to N itself. Thus the projective completion of $\mathbb{R}$, which we now call $\mathbb{RP}^1$, is *topologically the same* as the circle, in the sense that there is a continuous one-to-one correspondence between them. Moreover, we can understand projective completion of $\mathbb{R}$ topologically as a process of adding one "point" that is "approached" as one tends to infinity, in either direction, along $\mathbb{R}$, for as x tends to infinity in either direction, x' tends to the same point, N, on the circle.

We can now view projective completion of $\mathbb{C}$ in the same way using Figure 15.4, which shows the so-called *stereographic projection* of the plane $\mathbb{C}$ into a sphere. Each point $z \in \mathbb{C}$ is projected to a point z' on the tangential sphere S by the ray through z and the north pole N of S. This establishes a continuous one-to-one correspondence between points z of $\mathbb{C}$ and points $z' \neq N$ on S. Moreover, as z tends to infinity in any direction, z' tends to N; hence the projective completion of $\mathbb{CP}^1$ of $\mathbb{C}$ is topologically the same as the complete sphere S, with the point at ∞ of $\mathbb{C}$ corresponding to N.

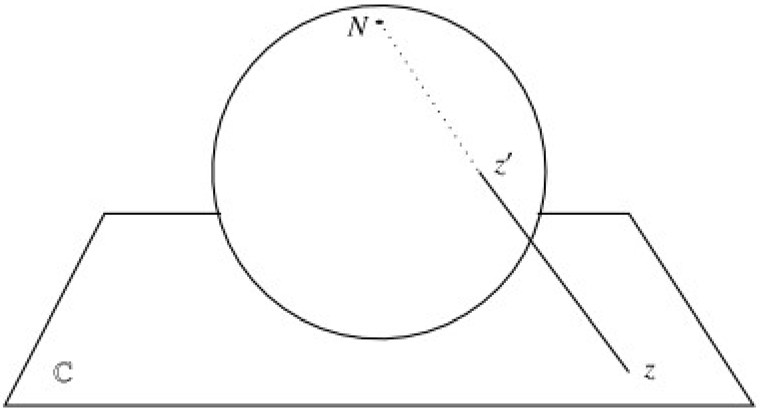

Figure 15.4: The complex projective line

Since one also wants to complete $\mathbb{C}$ by a point ∞ in this way for complex analysis, geometry and analysis are both served by passing from $\mathbb{C}$ to $\mathbb{CP}^1$. Gauss seems to have been the first to appreciate the advantages of $\mathbb{C} \cup \{\infty\}$ over $\mathbb{C}$; hence one often calls $\mathbb{CP}^1$ the *Gauss sphere* in analysis. (Unfortunately, only a few unpublished, undated fragments of Gauss's work on this topic seem to have survived; see Gauss (1819).) Algebraic geometers call $\mathbb{CP}^1$ the (complex) projective line, since it is the formal equivalent of a real line, even though it is topologically a surface. Similarly, complex curves are topologically surfaces, known to analysts as *Riemann surfaces*, though algebraic geometers prefer to call them "curves."

The "surface" viewpoint is helpful when studying intrinsic properties of complex curves. For example, *genus* (introduced in connection with parameterization in Sections 11.3 to 11.5) turns out to have a very simple meaning in the topology of surfaces (see Section 15.4). On the other hand, the "curve" viewpoint is helpful when studying intersections of curves and their embedding in $\mathbb{C}\times\mathbb{C}$ or its projective completion $\mathbb{CP}^2$. Instead of trying to imagine two planes meeting in a single point of $\mathbb{C}\times\mathbb{C}$, for example, it is better to imagine the intersection as analogous to that of real lines in a real plane—as the single solution of two linear equations. After all, we are working with $\mathbb{C}$ to remove anomalies that occur with $\mathbb{R}$, not for the sake of doing something different, and we expect that much of the behavior of real curves will recur with complex ones.

Exercises

Since addition and multiplication are continuous functions, it is quite easy to find one-to-one continuous maps between certain complex algebraic curves and the sphere.

15.2.1 Show that the projective completion of the curve $Y = X^2$ is topologically a sphere by considering its parameterization

$$X = t, \quad Y = t^2,$$

where t ranges over the sphere $\mathbb{C} \cup \{\infty\}$. Namely, show that the mapping $t \mapsto (t, t^2)$ is one-to-one and continuous.

15.2.2 Similarly show that the projective completion of $Y^2 = X^3$ is topologically a sphere by considering its parameterization

$$X = t^2, \quad Y = t^3$$

and the continuous mapping $t \mapsto (t^2, t^3)$.

15.2.3 Consider the mapping of the t sphere onto the projective completion of $Y^2 = X^2(X + 1)$ defined by $t \mapsto P(t)$, where $P(t)$ is the third intersection of the curve with the line $Y = tX$ through the double point (found in Exercise 7.4.2).

Show that this mapping is continuous and that it is one-to-one except at the points $t = \pm 1$, which are both mapped to the point O on the curve. Conclude that the curve is topologically the same as a sphere with two points identified (Figure 15.5).

15.3 Branch Points

The key to the topological form of a complex curve $p(x, y) = 0$ lies in its *branch points*, the points α where the Newton–Puiseux expansion of y begins with a fractional power of $(x - \alpha)$ (see Section 10.5). The nature of

5- 2 3 N 4 ; .

16.1 Complex Functions

When Bombelli (1572) introduced complex numbers, he implicitly introduced complex functions as well. The solution y of the cubic equation $y^3 = py + q$,

$$y = \sqrt[3]{\frac{q}{2} + \sqrt{\left(\frac{q}{2}\right)^2 - \left(\frac{p}{3}\right)^3}} + \sqrt[3]{\frac{q}{2} - \sqrt{\left(\frac{q}{2}\right)^2 - \left(\frac{p}{3}\right)^3}},$$

involves the cube root of a complex argument when $(q/2)^2 < (p/3)^3$. It could have been a revelation to see that complex numbers explain the coincidence of algebraic (Cardano) and geometric (Viète) solutions of the cubic equation, and more generally the Leibniz–de Moivre theorem that

$$x = \frac{1}{2}\sqrt[n]{y + \sqrt{y^2 - 1}} + \frac{1}{2}\sqrt[n]{y - \sqrt{y^2 - 1}},$$

when $x = \sin\theta$ and $y = \sin n\theta$ (Section 6.6). In the case of the cubic, this revelation can now be savored in Needham (1997), pp. 59–60. But mathematicians were not concerned about the meaning of these complex functions as long as they produced results that could be checked by algebra.

The need to *understand* complex functions became pressing only with transcendental functions, particularly those defined by integration. A key example is the logarithm function, which comes from integrating $dz/(1+z)$. Once this function was understood, the reason for algebraic miracles like the Leibniz–de Moivre theorem became much clearer.

Johann Bernoulli (1702) opened the story of the complex logarithm when he noted that

$$\frac{dz}{1+z^2} = \frac{dz}{2(1 + z\sqrt{-1})} + \frac{dz}{2(1 - z\sqrt{-1})}$$

and drew the conclusion that "imaginary logarithms express real circular sectors." He did not actually perform the integration, but he may have found

$$\tan^{-1} z = \frac{1}{2i}\log\frac{i-z}{i+z},$$

since Euler gives him credit for a similar formula when writing to him in Euler (1728b). However, this may have been the young Euler's deference to his former teacher, because Johann Bernoulli showed poor understanding of logarithms as the correspondence continued. He persistently claimed that $\log(-x) = \log(x)$ on the grounds that

$$\frac{d}{dx}\log(-x) = \frac{1}{x} = \frac{d}{dx}\log(x)$$

despite a reminder from Euler (1728b) that equality of derivatives does not imply equality of integrals. Euler went on to suggest that the complex logarithm had infinitely many values.

In the meantime, Cotes (1714) had also discovered a relation between complex logarithms and circular functions:

$$\log(\cos x + i\sin x) = ix.$$

Recognizing the importance of this result, he entitled his work *Harmonia mensurarum* (Harmony of measures). The "measures" in question were the logarithm and inverse tangent functions, which "measure" the hyperbola and the circle, respectively, via the integrals $\int dx/(1+x)$ and $\int dx/(1+x^2)$. A wide class of integrals had been reduced to these two types, but it was not understood why two apparently unrelated "measures" should be required. Cotes's result was the first (apart from the near-miss of Johann Bernoulli (1702)) to relate the two, showing that in the wider domain of complex functions the logarithm and inverse circular functions are essentially the same.

The most compact statement of their relationship was attained around 1740, when Euler shifted attention from the logarithm function to its inverse, the exponential function. The definitive formula

$$e^{ix} = \cos x + i\sin x$$

was first published by Euler (1748a), who derived it by comparing series expansions of both sides. Euler's formulation in terms of the single-valued function e^{ix} gave a simple explanation of the many values of the logarithm (which Cotes had missed) as a consequence of the periodicity of cos and sin. A direct explanation, based on the definition of log as an integral, was not possible until Gauss (1811) clarified the meaning of complex integrals and pointed out their dependence on the path of integration (see Section 16.3).

Euler's formula also shows that

$$(\cos x + i\sin x)^n = e^{inx} = \cos nx + i\sin nx$$

and hence gives a deeper explanation of the Leibniz–de Moivre formula. More generally, the addition theorems for cos and sin (Section 12.4) could be seen as consequences of the much simpler addition formula for the exponential function

$$e^{u+v} = e^u \cdot e^v.$$

The imaginary function e^{ix} was so much more coherent than its real constituents $\cos x$ and $\sin x$ that it was difficult to do without it, and Euler's formula gave mathematicians a strong push toward the eventual acceptance of complex numbers. A more detailed account of the role of the logarithm and exponential functions in the development of complex numbers may be found in Cajori (1913).

At almost the same time that Euler elucidated cos and sin, d'Alembert found many real functions occurring naturally in pairs as the real and imaginary parts of complex functions—in hydrodynamics. As mentioned in Section 13.7, d'Alembert (1752) discovered the equations

$$\frac{\partial P}{\partial y} - \frac{\partial Q}{\partial x} = 0, \tag{1}$$

$$\frac{\partial P}{\partial x} + \frac{\partial Q}{\partial y} = 0 \tag{2}$$

relating the velocity components P, Q in two-dimensional steady irrotational fluid flow. Equations (1) and (2) come from the requirements that $Q\,dx + P\,dy$ and $P\,dx - Q\,dy$ be complete differentials, in which case another complete differential is

$$Q\,dx + P\,dy + i(P\,dx - Q\,dy) = (Q + iP)\left(dx + \frac{dy}{i}\right) = (Q + iP)d\left(x + \frac{y}{i}\right).$$

D'Alembert concluded that this means $Q + iP$ is a function f of $x + y/i$, so that $Q = \mathrm{Re}(f)$ and $P = \mathrm{Im}(f)$.

To feel the force of this result, one has to forget the modern definition of function, under which $u(x, y) + iv(x, y)$ is a function of $x + iy$ for *any* functions u, v. In the 18th-century context, a "function" $f(x + iy)$ of $x + iy$ was calculable from $x + iy$ by elementary operations; at worst, $f(x + iy)$ was a power series in $x + iy$. This imposes a strong constraint on u, v, namely that

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}.$$

These were just the equations d'Alembert found in his hydrodynamical investigations, but they came to be named the Cauchy–Riemann equations, because the latter mathematicians stressed their key role in the study of complex functions. The concept of complex function was solidified when Cauchy (1837) showed that a function $f(z)$, where $z = x + iy$, merely had to be differentiable in order to be expressible as a power series in z. Thus it suffices to define a complex function $f(z)$ to be one that is differentiable with respect to z in order to guarantee that f is defined with 18th-century strictness. It follows, in particular, that the first derivative of f entails derivatives of all orders and that the values of f in any neighborhood determine its values everywhere. This "rigidity" in the notion of complex function is enough of a constraint to enable nontrivial properties to be proved, but at the same time it leaves enough flexibility—one might say "fluidity"—to cover important general situations.

EXERCISES

Euler's derivation of $e^{ix} = \cos x + i\sin x$ is easy to explain using the power series

$$e^y = 1 + \frac{y}{1!} + \frac{y^2}{2!} + \frac{y^3}{3!} + \cdots$$

and

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots$$

found in Section 9.5.

16.1.1 Assuming that the series for e^y is also valid for $y = ix$, show that

$$e^{ix} = \left(1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots\right) + i\left(x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots\right).$$

16.1.2 Assuming it is valid to differentiate the sine series term by term, show that

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots,$$

and hence that $e^{ix} = \cos x + i\sin x$.

Another consequence of $e^{ix} = \cos x + i\sin x$ is that $i = \cos\frac{\pi}{2} + i\sin\frac{\pi}{2} = e^{i\pi/2}$, which allows us to evaluate the outlandish number i^i.

16.1.3 Show that i^i has a real value (Euler (1746)). What is it?

16.1.4 Using the fact that $e^{2in\pi} = 1$ for any integer n, give a formula for all values of i^i (Euler (1746)).

17.5.2 Show that the circles on the cone, in planes perpendicular to its axis, are *not* geodesics.

17.5.3 Show that there are nonsmooth geodesics on the cone, that is, curves of geodesic curvature zero except at certain points where they have no tangent.

17.6 The Gauss–Bonnet Theorem

In Section 17.2 we observed that

$$\int_C \kappa\, ds = 2\pi$$

for a simple closed curve C in the plane. This result has a profound generalization to curved surfaces known as the *Gauss–Bonnet* theorem. On a curved surface, κ must be replaced by the geodesic curvature κ_g, and the theorem states that

$$\int_C \kappa_g\, ds = 2\pi - \iint_{\mathcal{R}} \kappa_1 \kappa_2\, dA,$$

where A denotes area and $\mathcal{R}$ is the region enclosed by C (Bonnet (1848)). Gauss himself published only a special case, or rather the limit of a special case, in which C is a geodesic triangle. In this case, of course, $\kappa_g = 0$ along the sides of C, and κ_g becomes infinite at the corners. By rounding off the corners by small arcs ds, one sees (Figure 17.10) that

$$\int_{C^*} \kappa_g\, ds \cong \alpha' + \beta' + \gamma',$$

where α', β', γ' are the external angles of the triangle and C^* is the rounded approximation to the triangle C.

Then by letting the size of the round-offs tend to zero one gets

$$\int_{C^*} \kappa_g\, ds = \alpha' + \beta' + \gamma' = 3\pi - (\alpha + \beta + \gamma),$$

where α, β, γ are the internal angles of the triangle. Introducing the quantity

$$(\alpha + \beta + \gamma) - \pi,$$

called the *angular excess* of the triangle (because an ordinary triangle has angle sum π), we have

$$\int_C \kappa_g\, ds = 2\pi - \text{angular excess},$$

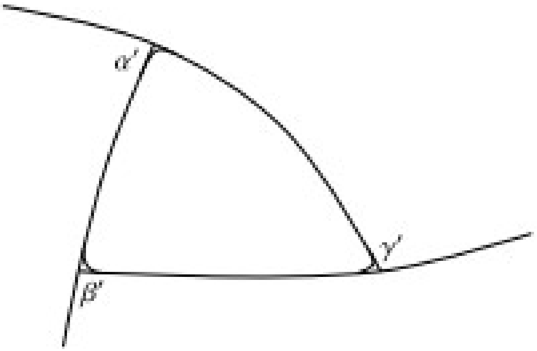

Figure 17.10: Rounding off a geodesic triangle

and the result of Gauss (1827) was that

$$\text{angular excess} = \iint_{\mathcal{R}} \kappa_1\kappa_2 \, dA.$$

We see that the *integral* of the Gaussian curvature has a more elementary geometric meaning than the curvature $\kappa_1\kappa_2$. It appears, in fact, that Gauss thought about angular excess first, then the curvature integral, and only last about the curvature itself. The decomposition into principal curvatures probably came later, when he reworked his geometric ideas into analytic form, reversing the order of discovery in the process. Dombrowski (1979) made a plausible reconstruction of the original approach, using clues from the unpublished work of Gauss.

The role of angular excess can be seen more plainly in the case of constant curvature $\kappa_1\kappa_2 = c$. In this case

$$\text{angular excess} = c \times \text{area of } \mathcal{R},$$

so the angular excess gives a measure of area, a result Gauss claimed, in a letter (1846a), to have known in 1794. In fact, the special case of this result for the sphere was known to Thomas Harriot in 1603 (see Lohne (1979)). Harriot's elegant proof goes as follows (Figure 17.11).

Prolonging the sides of triangle ABC partitions the sphere into four pairs of congruent, diametrically opposite triangles (Figure 17.11a). We denote the area of ABC and its diametric opposite $A'B'C'$ by $\Delta_{\alpha\beta\gamma}$. The

α
$\Delta_{\alpha\beta\gamma}$
Δ_{α}
(b)

Figure 17.11: Area of a spherical triangle

other three pairs represent areas $\Delta_\alpha, \Delta_\beta, \Delta_\gamma$, which complement $\Delta_{\alpha\beta\gamma}$ in "slices" of the sphere of angles α, β, γ, respectively (Figure 17.11b).

Since the area of a slice is $2r^2$ times the angle, where r is the radius of the sphere, we have

$$\begin{aligned}\Delta_{\alpha\beta\gamma} + \Delta_\alpha &= 2r^2\alpha,\\ \Delta_{\alpha\beta\gamma} + \Delta_\beta &= 2r^2\beta,\\ \Delta_{\alpha\beta\gamma} + \Delta_\gamma &= 2r^2\gamma,\end{aligned}$$

whence, by addition,

$$3\Delta_{\alpha\beta\gamma} + (\Delta_\alpha + \Delta_\beta + \Delta_\gamma) = 2r^2(\alpha + \beta + \gamma). \tag{1}$$

On the other hand,

$$2(\Delta_{\alpha\beta\gamma} + \Delta_\alpha + \Delta_\beta + \Delta_\gamma) = \text{area of sphere} = 4\pi r^2,$$

and substituting this in (1) gives

$$\Delta_{\alpha\beta\gamma} = r^2(\alpha + \beta + \gamma - \pi)$$

as required, since $1/r^2$ = curvature of the sphere.

Gauss was interested in the counterpart of this result for negative curvature, in which case the angle sum of a triangle is less than π and one has angular *defect* rather than angular excess. His investigations in this case led him not only to Gaussian curvature but also to non-Euclidean geometry.

EXERCISES

It is surprising at first that area on the sphere should be measured by angles rather than lengths. However, there are general reasons (apart from the Gauss–Bonnet theorem) why area should be measured by angular excess, and this idea fails only where angular excess is zero—that is, in the Euclidean plane.

17.7.1 Consider a triangle Δ split into two triangles Δ_1 and Δ_2 by a line through a vertex. Show that

$$\text{excess}(\Delta) = \text{excess}(\Delta_1) + \text{excess}(\Delta_2).$$

17.7.2 Deduce from Exercise 17.7.1 that if any polygon Π is split into triangles Δ_i, then

$$\text{excess}(\Pi) = \text{excess}(\Delta_1) + \text{excess}(\Delta_2) + \cdots .$$

Thus the angular excess function has the same *additive* property as an area function. It can be shown that any additive function, provided it is continuous, is a constant multiple of area (see Bonola (1912), p. 46).

18.2 Spherical Geometry

In rejecting P_0 because of its incompatibility with infinite lines, Saccheri avoided having to consider the most natural geometry in which P_0 holds, that of the sphere with great circles as "lines." Spherical geometry had been cultivated since ancient times to meet the needs of astronomers and navigators, and formulas for the side lengths and areas of spherical triangles were well known. But the sphere was considered part of Euclid's spatial geometry, so the axiomatic significance of spherical geometry was at first ignored. What did happen, though, was that the first explorations of Axiom P_2 were guided by the analogy of the sphere.

Lambert (1766) made the striking discovery that Axiom P_2 implies that the area of a triangle with angles α, β, γ is proportional to $\pi - (\alpha + \beta + \gamma)$, its angular defect. In other words,

$$\text{area} = -R^2(\alpha + \beta + \gamma - \pi)$$

for some positive constant R^2. Having rediscovered Harriot's theorem that

$$\text{area} = R^2(\alpha + \beta + \gamma - \pi)$$

for a triangle on the sphere of radius R, Lambert mused that one "could almost conclude that the new geometry would be true on a sphere of imaginary radius." What a sphere of radius iR might be was never explained, but the idea of using complex numbers to generate the formulas of a hypothetical geometry proved fruitful.

It was found that formulas derived from Axiom P_2 could also be obtained by replacing R by iR in corresponding formulas of spherical geometry. For example, Gauss (1831) deduced from Axiom P_2 that the circumference of a circle of radius r is $2\pi R \sinh r/R$. The same result follows by replacing R by iR in $2\pi R \sin r/R$, which is the circumference of a circle of radius r on the sphere (where, of course, r is measured *on* the spherical surface; see Exercise 18.2.1).

Klein (1871) called the geometry of Axiom P_2 *hyperbolic*. One reason for this is that its formulas involve hyperbolic functions, whereas those of spherical geometry involve circular functions. Lambert (1766) introduced the hyperbolic functions and noted their analogy with the circular functions, but he did not follow through with a complete translation of spherical formulas into hyperbolic formulas. This was first done by Taurinus

(1826), one of a small circle who corresponded with Gauss on geometric questions.

This gave hyperbolic geometry a second leg to stand on, but there was still nothing solid under its feet. Neither Gauss nor Taurinus seemed confident of finding a convincing interpretation of hyperbolic geometry, even though Gauss (1827) came remarkably close with the "Gauss–Bonnet" theorem. As mentioned in Section 17.6, this theorem shows that surfaces of constant negative curvature give a geometry in which angular defect is proportional to area, and Gauss knew that the pseudosphere is such a surface. Gauss's student Minding (1840) even showed that the hyperbolic formulas for triangles hold on the pseudosphere, but no one at that time commented on the likely importance of this result for hyperbolic geometry. Perhaps it was clear that the pseudosphere cannot serve as a "plane," because it is infinite in only one direction. Only in 1868, when Beltrami extended the pseudosphere to a true *hyperbolic plane*—a surface locally like the pseudosphere but infinite in all directions—was hyperbolic geometry finally placed on a firm foundation.

EXERCISES

18.2.1 Prove that the circumference of the circle C of radius r on the sphere of radius R (Figure 18.4) is $2\pi R\sin(r/R)$.

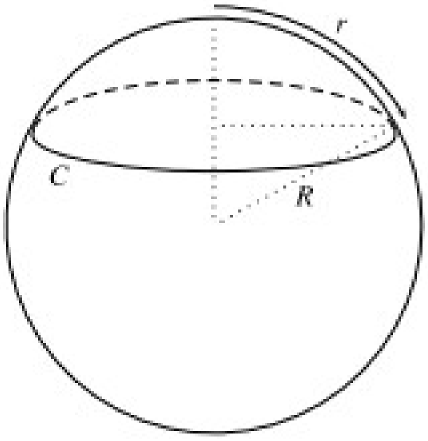

Figure 18.4: Radius and circumference on the sphere

18.2.2 Show that both $2\pi R\sin(r/R)$ and $2\pi R\sinh(r/R)$ tend to $2\pi r$ as $R \to \infty$.

These results show how even non-Euclidean geometry is "Euclidean in the small"—its formulas tend to the Euclidean formulas as size tends to zero. The same is true of the angle-sum formula for a triangle.

18.2.3 Deduce from Harriot's area formula that the angle sum of a spherical triangle tends to π as its size tends to zero.

18.3 Geometry of Bolyai and Lobachevsky

The most important contributors to hyperbolic geometry between Gauss and Beltrami were Lobachevsky and Bolyai, who published independent discoveries of the subject: Lobachevsky (1829) and János Bolyai (1832b). Because of their courage in advocating an unconventional geometry, Bolyai and Lobachevsky have been justly admired. Nevertheless, the immediate impact of their work was slight. Many of their results were already known to Gauss and his circle and could have been picked up from existing publications and personal contacts. Lambert (1766) and Taurinus (1826) were in print, and Bolyai's father, F. Bolyai, was a lifelong friend of Gauss, as was Lobachevsky's teacher Bartels. In any case their work, though more systematic and convincing than previous attempts, attracted very little attention at first. We have seen how the possibility of using differential geometry to justify hyperbolic geometry was overlooked until 1868. Up to that time, there seemed no reason to take hyperbolic geometry seriously.

In retrospect, of course, the theorems of Bolyai and Lobachevsky can be seen to unify the fragmentary results of their predecessors very nicely. They cover the basic relations between sides and angles of triangles (hyperbolic trigonometry), the measure of polygonal areas by angular defect, and formulas for circumference and area of circles. Lobachevsky (1836) broke new ground by finding volumes of polyhedra, which turn out to be far from elementary, involving the function $\int_0^\theta \log 2|\sin t|\,dt$.

Both Bolyai and Lobachevsky considered a three-dimensional space satisfying Axiom P_2 and made extensive use of a surface peculiar to this space, the *horosphere*. A horosphere is a "sphere with center at infinity," and it is *not* a hyperbolic plane. Wachter, a student of Gauss, observed in a letter of 1816 (published in Stäckel (1901)) that the geometry of the horosphere is in fact Euclidean. This astonishing result was rediscovered by Bolyai and Lobachevsky, and they anticipated that it would make Euclidean geometry subordinate to hyperbolic. We shall see in Section 18.5 how this view was vindicated in the work of Beltrami.

of each other. Gauss–Bonnet ⇒ Descartes by concentrating the curvature of a surface at vertices until it becomes a polyhedron, while Descartes ⇒ Gauss–Bonnet by increasing the number of vertices of a polyhedron until it becomes a smooth surface. It is interesting, though probably accidental, that Descartes actually uses the word "curvatura" to describe the exterior solid angle.

22.5 Euler Characteristic and Curvature

There is another, more "intrinsic," proof of Descartes's theorem that reveals the fact that total exterior solid angle is really $2\pi \times$ Euler characteristic. In fact, knowledge of the total exterior angle yields a proof of the Euler characteristic polyhedron formula. This seems to have been the way in which Descartes discovered his version of the formula.

The key step is to show that the exterior solid angle at a vertex P is expressible intrinsically as $2\pi - (\alpha_1 + \alpha_2 + \cdots + \alpha_n)$, where $\alpha_1, \alpha_2, \ldots, \alpha_n$ are the face angles that meet at P. These are *not* the angles $\alpha'_1, \alpha'_2, \ldots, \alpha'_n$ between the planes that bound the exterior solid angle, but it turns out (Exercise 22.5.1) that

$$\alpha_i + \alpha'_i = \pi$$

for each i, whence the measure of the exterior solid angle, which comes from $\alpha'_i + \alpha'_2 + \cdots + \alpha'_n$ by Harriot's theorem (Section 17.6), also comes from $\alpha_1 + \alpha_2 + \cdots + \alpha_n$.

Knowing now that the exterior solid angle at P equals $2\pi - \sum$ face angles at P, we get

$$\text{total exterior solid angle} = 2\pi V - \sum \text{all face angles},$$

where V is the total number of vertices. By grouping the face angles according to the types of faces, we also find (Exercise 22.5.2) that

$$\sum \text{all face angles} = \pi(2E - 2F),$$

whence

$$\begin{aligned}\text{total exterior solid angle} &= 2\pi(V - E + F)\\ &= 2\pi \times \text{Euler characteristic}.\end{aligned}$$

In the case of convex polyhedra, where we already know that total exterior solid angle $= 4\pi$, this gives Euler characteristic $= 2$. More importantly, the derivation is valid for polyhedra of arbitrary Euler characteristic, showing that the total exterior solid angle is really the *same* as the Euler characteristic, up to a constant multiple.

There is a similar intrinsic proof of the Gauss–Bonnet theorem, again valid for arbitrary Euler characteristic, which shows that

$$\text{total curvature} = \iint_S \kappa_1 \kappa_2 \, dA = 2\pi \times \text{Euler characteristic}$$

(Exercise 22.5.3). Legendre's (1794) proof of the Euler polyhedron formula is the special case of the argument for constant curvature.

Thus the Euler characteristic regulates the total curvature of a surface. In particular, if the curvature is constant, it must have the same sign as the Euler characteristic. This in turn has implications for the geometry of the surface. As we saw in Section 17.4, surfaces of constant positive curvature have spherical geometry, those of zero curvature have Euclidean geometry, and those of negative curvature have hyperbolic geometry. In the next section we shall see that there is a natural way to impose constant curvature on surfaces of arbitrary Euler characteristic. It will then follow that the natural geometry of a surface is spherical, Euclidean, or hyperbolic according as its Euler characteristic is positive, zero, or negative. Moreover, if the absolute value of the curvature is taken to be 1, then the Gauss–Bonnet theorem gives

$$\text{area} = |2\pi \times \text{Euler characteristic}|.$$

This makes surface topology completely subordinate to geometry, at least for orientable surfaces, because it says that the topology of a surface is completely determined by the sign of its curvature and its area.

These results were implicit in the work of Poincaré and Klein in the 1880s. Perhaps Klein was the first to see clearly how the geometry of a surface determines its topology (see, for example, Klein (1928), p. 264).

Exercises

Figure 22.8 shows the region around a vertex P of a polyhedron and the exterior solid angle of P centered at O and bounded by the planes OAB, OBC, OCA perpendicular to the edges through P.

22.5.1 Show that there are right angles where indicated, and hence that

$$\alpha + \alpha' = \pi, \quad \beta + \beta' = \pi, \quad \gamma + \gamma' = \pi.$$

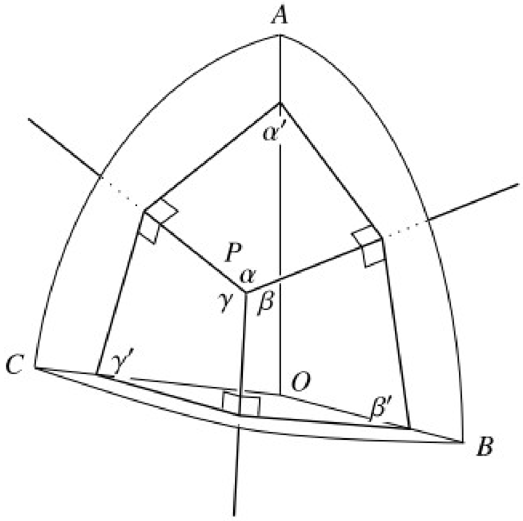

Figure 22.8: The vertex region of a polyhedron

Now to relate face angles to E and F, it helps to write

$$F = F_3 + F_4 + F_5 + \cdots,$$

where F_3 = number of 3-gon faces, F_4 = number of 4-gon faces, and so on.

22.5.2 Show that

$$E = \frac{1}{2}(3F_3 + 4F_4 + 5F_5 + \cdots),$$

and deduce that in an ordinary polyhedron (that is, one with flat faces),

$$\sum \text{all face angles} = \pi(2E - 2F),$$

using the fact the angle sum of an n-gon is $(n-2)\pi$.

22.5.3 Prove the global form of the Gauss–Bonnet theorem,

$$\iint_S \kappa_1\kappa_2 \, dA = 2\pi \times \text{Euler characteristic},$$

by partitioning the closed surface $\mathcal{S}$ into geodesic polygons and applying the ordinary form of the Gauss–Bonnet theorem (Section 17.6).

22.6 Surfaces and Planes

In Section 16.5 we noticed that an elliptic function defines a mapping of a plane onto a torus. Such mappings are also interesting in the topological

)) -)) =) 9+))-) 2. - 73

We got this result by making the angles α in the two triangles coincide. If we make the angles β coincide instead, we similarly find that the sides opposite to α and γ are proportional. Thus, in fact, *all corresponding sides of similar triangles are proportional*. □

This consequence of the Thales theorem has many implications. In everyday life, it underlies the existence of scale maps, house plans, engineering drawings, and so on. In pure geometry, its implications are even more varied. Here is just one, which shows why square roots and irrational numbers turn up in geometry.

The diagonal of the unit square is $\sqrt{2}$

The diagonals of the unit square cut it into four quarters, each of which is a triangle similar to the half square cut off by a diagonal (Figure 1.17).

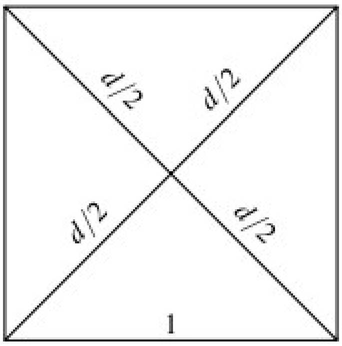

Figure 1.17: Quarters and halves of the square

Each of the triangles in question has one right angle and two half right angles, so it follows from the theorem above that corresponding sides of any two of these triangles are proportional. In particular, if we take the half square, with short side 1 and long side d, and compare it with the quarter square, with short side $d/2$ and long side 1, we get

$$\frac{\text{short}}{\text{long}} = \frac{1}{d} = \frac{d/2}{1}.$$

Multiplying both sides of the equation by $2d$ gives $2 = d^2$, so $d = \sqrt{2}$. □

The great, but disturbing, discovery of the Pythagoreans is that $\sqrt{2}$ *is irrational*. That is, there are no natural numbers m and n such $\sqrt{2} = m/n$.

If there are such m and n we can assume that they have no common divisor, and then the assumption $\sqrt{2} = m/n$ implies

	$2 = m^2/n^2$	squaring both sides
hence	$m^2 = 2n^2$	multiplying both sides by n^2
hence	m^2 is even	
hence	m is even	since the square of an odd number is odd
hence	$m = 2l$	for some natural number l
hence	$m^2 = 4l^2 = 2n^2$	
hence	$n^2 = 2l^2$	
hence	n^2 is even	
hence	n is even	since the square of an odd number is odd.

Thus, m and n have the common divisor 2, contrary to assumption. Our original assumption is therefore false, so there are no natural numbers m and n such that $\sqrt{2} = m/n$. □

Lengths, products, and area

Geometry obviously has to include the diagonal of the unit square, hence *geometry includes the study of irrational lengths.* This discovery troubled the ancient Greeks, because they did not believe that irrational lengths could be treated like numbers. In particular, the idea of interpreting the product of line segments as another line segment is *not* in Euclid. It first appears in Descartes' *Géométrie* of 1637, where algebra is used systematically in geometry for the first time.

The Greeks viewed the product of line segments a and b as the *rectangle* with perpendicular sides a and b. If lengths are not necessarily numbers, then the product of two lengths is best interpreted as an area, and the product of three lengths as a volume—but then the product of four lengths seems to have no meaning at all. This difficulty perhaps explains why algebra appeared comparatively late in the development of geometry. On the other hand, interpreting the product of lengths as an area gives some remarkable insights, as we will see in Chapter 2. So it is also possible that algebra had to wait until the Greek concept of product had exhausted its usefulness.

Exercises

In general, two geometric figures are called similar if one is a magnification of the other. Thus, two rectangles are similar if the ratio $\frac{\text{long side}}{\text{short side}}$ is the same for both.

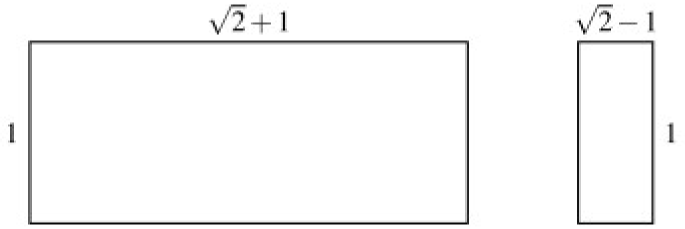

Figure 1.18: A pair of similar rectangles

1.5.1 Show that $\frac{\sqrt{2}+1}{1} = \frac{1}{\sqrt{2}-1}$ and hence that the two rectangles in Figure 1.18 are similar.

1.5.2 Deduce that if a rectangle with long side a and short side b has the same shape as the two above, then so has the rectangle with long side b and short side $a-2b$.

This simple observation gives another proof that $\sqrt{2}$ is irrational:

1.5.3 Suppose that $\sqrt{2}+1 = m/n$, where m and n are natural numbers with m as small as possible. Deduce from Exercise 1.5.2 that we also have $\sqrt{2}+1 = n/(m-2n)$. This is a contradiction. Why?

1.5.4 It follows from Exercise 1.5.3 that $\sqrt{2}+1$ is irrational. Why does this imply that $\sqrt{2}$ is irrational?

1.6 Discussion

Euclid's *Elements* is the most influential book in the history of mathematics, and anyone interested in geometry should own a copy. It is not easy reading, but you will find yourself returning to it year after year and noticing something new. The standard edition in English is Heath's translation, which is now available as a Dover reprint of the 1925 Cambridge University Press edition. This reprint is carried by many bookstores; I have even seen it for sale at Los Angeles airport! Its main drawback is its size—three bulky volumes—due to the fact that more than half the content consists of

Heath's commentary. You can find the Heath translation *without* the commentary in the Britannica *Great Books of the Western World*, Volume 11. These books can often be found in used bookstores. Another, more recent, one-volume edition of the Heath translation is *Euclid's Elements*, edited by Dana Densmore and published by Green Lion Press in 2003.

A second (slight) drawback of the Heath edition is that it is about 80 years old and beginning to sound a little antiquated. Heath's English is sometimes quaint, and his commentary does not draw on modern research in geometry. He does not even mention some important advances that were known to experts in 1925. For this reason, a modern version of the *Elements* is desirable. A perfect version for the 21st century does not yet exist, but there is a nice concise web version by David Joyce at

`http://aleph0.clarkeu.edu/~djoyce/java/elements/elements.html`

This *Elements* has a small amount of commentary, but I mainly recommend it for proofs in simple modern English and nice diagrams. The diagrams are "variable" by dragging points on the screen, so each diagram represents all possible situations covered by a theorem.

For modern commentary on Euclid, I recommend two books: *Euclid: the Creation of Mathematics* by Benno Artmann and *Geometry: Euclid and Beyond* by Robin Hartshorne, published by Springer-Verlag in 1999 and 2000, respectively. Both books take Euclid as their starting point. Artmann mainly fills in the Greek background, although he also takes care to make it understandable to modern readers. Hartshorne is more concerned with what came after Euclid, and he gives a very thorough analysis of the gaps in Euclid and the ways they were filled by modern mathematicians. You will find Hartshorne useful supplementary reading for Chapters 2 and 3, where we examine the logical structure of the *Elements* and some of its gaps.

The climax of the *Elements* is the theory of regular polyhedra in Book XIII. Only five regular polyhedra exist, and they are shown in Figure 1.19. Notice that three of them are built from equilateral triangles, one from squares, and one from regular pentagons. This remarkable phenomenon underlines the importance of equilateral triangles and squares, and draws attention to the regular pentagon. In Chapter 2, we show how to construct it. Some geometers believe that the material in the *Elements* was chosen very much with the theory of regular polyhedra in mind. For example, Euclid wants to construct the equilateral triangle, square, and pentagon in order to construct the regular polyhedra.

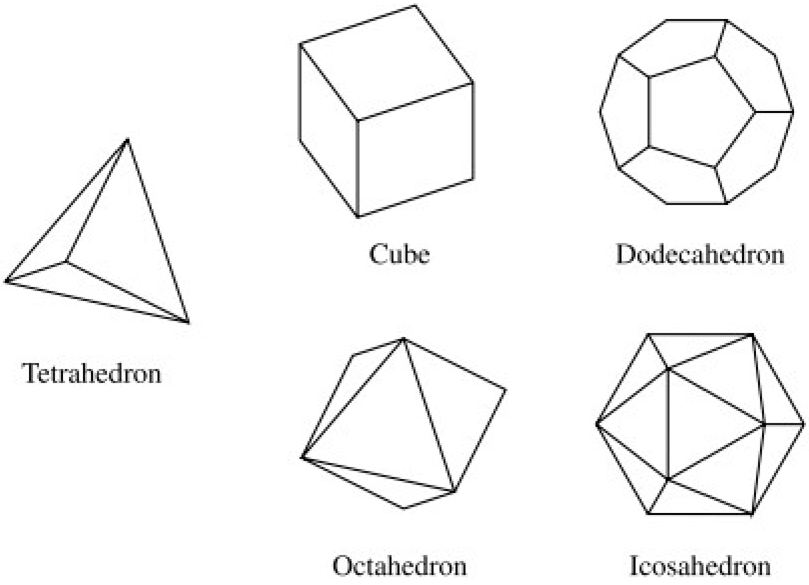

Figure 1.19: The regular polyhedra

It is fortunate that Euclid did not need regular polygons more complex than the pentagon, because none were constructed until modern times. The regular 17-gon was constructed by the 19-year-old Carl Friedrich Gauss in 1796, and his discovery was the key to the "question arising" from the construction of the equilateral triangle in Section 1.2: for which n is the regular n-gon constructible? Gauss showed (with some steps filled in by Pierre Wantzel in 1837) that a regular polygon with a prime number p of sides is constructible just in case p is of the form $2^{2^m}+1$. This result gives three constructible p-gons not known to the Greeks, because

$$2^4+1=17, \quad 2^8+1=257, \quad 2^{16}+1=65537$$

are all prime numbers. But no larger prime numbers of the form $2^{2^m}+1$ are known! Thus we do not know whether a larger constructible p-gon exists.

These results show that the *Elements* is not all of geometry, even if one accepts the same subject matter as Euclid. To see where Euclid fits in the general panorama of geometry, I recommend the books *Geometry and the Imagination* by D. Hilbert and S. Cohn-Vossen, and *Introduction to Geometry* by H. S. M. Coxeter (Wiley, 1969).

and z_- which both lie at the intersection of the three radical planes. The barycentric coordinates γ_i, $i \in \{1,2,3\}$, of $z_0 = (z_+ + z_-)/2$ are calculated in Eq. (4.18) from Eqs. (4.14) and (4.15), where T_{123} is the surface of the triangle c_1, c_2, c_3 and i, j, k are circular permutations of $1, 2, 3$. We get also the length of the segment $z^+ - z^-$ in Eq. (4.19), and then we deduce Theorem 4.4:

$$\begin{aligned}16T_{123}^2\gamma_i = & -2R_i^2\|c_j-c_k\|^2\\ & + R_j^2(\|c_j-c_k\|^2+\|c_k-c_i\|^2-\|c_i-c_j\|^2)\\ & + R_k^2(\|c_j-c_k\|^2-\|c_k-c_i\|^2+\|c_i-c_j\|^2)\\ & + \|c_j-c_k\|^2(-\|c_j-c_k\|^2+\|c_k-c_i\|^2+\|c_i-c_j\|^2),\end{aligned} \tag{4.18}$$

5- 7 2T/3 6 / E , 6
,9 Y) 5 4))))) Q

$$\left\|\frac{z_+ - z_-}{2}\right\|^2 = \frac{R_1^2 + R_2^2 + R_3^2}{3} - \left\|z_0 - \frac{c_1 + c_2 + c_3}{3}\right\|^2 - \frac{\|c_2 - c_1\|^2 + \|c_3 - c_2\|^2 + \|c_1 - c_3\|^2}{9}. \tag{4.19}$$

Theorem 4.4. *The convex domain defined by the configuration of Fig. 4.5d exists if and only if the quantity at the right member of Eq. (4.19) is positive.*

In the case of Fig. 4.5d, the point $z_0 = (z_+ + z_-)/2$ is interior to the intersection of the three spheres because this intersection is convex. Then, z_0, z_+, z_- and the three contact points on the boundary of the sphere intersection in the plane c_1, c_2, c_3 define a partition of the intersection into six parts, each one being the intersection between one sphere and one trihedron. Each of the six trihedra originates in z_0 and is bounded by two radical planes and by the plane c_1, c_2, c_3. We denote by $x_{ij}^{(k)}$ each of the contact points at the intersection of the great circles of spheres i and j located in the interior of the sphere k, where i, j, k are circular permutations of $1, 2, 3$. Thus the trihedra are defined by the half lines sets:

$$\left\{z_0 \to x_{31}^{(2)}, z_0 \to x_{12}^{(3)}, z_0 \to z_+\right\}$$

$$\left\{z_0 \to x_{12}^{(3)}, z_0 \to x_{23}^{(1)}, z_0 \to z_+\right\}$$

$$\left\{z_0 \to x_{23}^{(1)}, z_0 \to x_{31}^{(2)}, z_0 \to z_+\right\}$$

and their mirror symmetric images through the plane c_1, c_2, c_3:

$$\left\{z_0 \to x_{31}^{(2)}, z_0 \to x_{12}^{(3)}, z_0 \to z_-\right\}$$

$$\left\{z_0 \to x_{12}^{(3)}, z_0 \to x_{23}^{(1)}, z_0 \to z_-\right\}$$

$$\left\{z_0 \to x_{23}^{(1)}, z_0 \to x_{31}^{(2)}, z_0 \to z_-\right\}.$$

The six above trihedra intersect respectively with the sphere 1, 2, 3, 1, 2, 3.

It follows that the calculation of V_{123} and S_{123} can be done through the calculation of the portion of the area of a sphere defined by its intersection with a trihedron having its origin in the interior of the sphere. This latter calculation will be shown to be required in the case of four intersecting spheres and is done analytically in Sect. 4.2.6 using the Gauss–Bonnet theorem.

Several analytical treatments of up to three intersecting spheres appeared in the literature. Some do not involve the Gauss–Bonnet theorem [17, 18, 49], but most involve it [2, 7, 8, 24, 36, 47]. These latter are mainly based on [7] for the surfaces and on [8] for the volumes. As shown in Sect. 4.2.7, neglecting the intersections of order four and higher is numerically not acceptable for van der Waals surfaces and volumes calculation.

4.2.5 Intersections of Order 4

We set $n = 4$ and we iterate again Eqs. (4.12) and (4.13):

$$\begin{aligned} V &= V_1 + V_2 + V_3 + V_4 - V_{12} - V_{13} - V_{14} - V_{23} - V_{24} - V_{34} \\ &\quad + V_{123} + V_{124} + V_{134} + V_{234} - V_{1234}, \end{aligned} \tag{4.20}$$

$$\begin{aligned} S &= S_1 + S_2 + S_3 + S_4 - S_{12} - S_{13} - S_{14} - S_{23} - S_{24} - S_{34} \\ &\quad + S_{123} + S_{124} + S_{134} + S_{234} - S_{1234}. \end{aligned} \tag{4.21}$$

We set $d = 3$. For clarity, we do not enumerate all topological configurations generated by four intersecting spheres. If any of the four triplets of spheres is not in the configuration of Fig. 4.5d, we know how to calculate V_{1234} and S_{1234}.

Assuming that the four sphere triplets are in the configuration of Fig. 4.5d, we can classify the topological configurations via locating the four pairs of two contact points $z_+^{(ijk)}$ and $z_-^{(ijk)}$ at the intersections of the boundaries of the three spheres i, j, k, $1 \le i < j < k \le 4$. Each of the two contact points defined by a triplet of spheres can be inside or outside the fourth sphere (we still neglect tangencies and multiplicities). We consider the possible locations of the six remaining contact points. When all of them are inside a sphere, one sphere is included in the union of the three other ones. When all the six remaining contact points are outside a sphere, either the intersection of three spheres is included in the remaining one or the 4-order intersection is empty. This case of empty intersection was called an empty simplicial topology (EST) in [37]. If it happens for some triplet i, j, k that $z_+^{(ijk)}$ is inside the fourth sphere and $z_-^{(ijk)}$ is outside, or conversely, then that happens for all the other triplets: there are three contact points inside a sphere and three outside (this is the general case of intersection of four spheres). The two remaining cases correspond in fact to the same configuration: the intersection of two spheres is included in the union of the two other ones.

To summarize, when the four sphere triplets are in the configuration of Fig. 4.5d, the possible configurations for a non-empty 4-order intersection are:

1. One sphere is included in the union of the three other ones.
2. The intersection of two spheres is included in the union of the two other ones.
3. The intersection of three spheres is included in the remaining one.
4. None of the above ones: general case.

Calculating the 4-order intersection reduces to calculate the 3-order intersections in the cases of configurations 1,2,3. The total number of pairs of interior contact points for these latter configurations are respectively 3,2,1, and the total number of pairs of exterior contact points are respectively 1,2,3. Only the EST configuration has 4 exterior contact point pairs.

In the general case, the domain of the 4-order intersection is bounded by four spherical triangles separated by six arcs of circle and intersecting at four contact points: $z^{(123)}$, $z^{(124)}$, $z^{(134)}$, $z^{(234)}$. This convex domain is topologically similar to a tetrahedron. From Theorem 4.3, there is a unique point z_0 at the intersection of the 6 radical planes. Its barycentric coordinates are computed from Eq. (4.14) and (4.15). The point z_0 is interior to the convex domain of the 4-order intersection. This latter is partitioned into four parts, each one being the intersection of one sphere and one trihedron originating in z_0.

These trihedra, which intersect respectively the spheres 1, 2, 3, 4, are:

$$\{z_0 \to x^{(123)}, z_0 \to x^{(124)}, z_0 \to z^{(134)}\},$$
$$\{z_0 \to x^{(123)}, z_0 \to x^{(124)}, z_0 \to z^{(234)}\},$$
$$\{z_0 \to x^{(123)}, z_0 \to x^{(134)}, z_0 \to z^{(234)}\},$$
$$\{z_0 \to x^{(124)}, z_0 \to x^{(134)}, z_0 \to z^{(234)}\}.$$

It follows that the calculation of V_{1234} and S_{1234} can be done through the calculation of the portion of the area of a sphere defined by its intersection with a trihedron having its origin in the interior of the sphere. This latter calculation is done analytically in Sect. 4.2.6 using the Gauss–Bonnet theorem. An analytical treatment of the four-sphere intersection without invoking the Gauss–Bonnet theorem was reported [27].

4.2.6 *Intersection of a Sphere with a Dihedron or with Trihedron*

We consider a sphere of center c and radius R intersecting a salient trihedron of origin z inside the sphere. The trihedron intersects the boundary of the sphere at x_1, x_2, x_3, these three points being ordered in the direct sense when referred to z as origin. We look for the calculation of the volume V_{st} of the intersection and for the surface S_{st} of the spherical triangle on the boundary of the sphere. This spherical triangle is bounded by the oriented arcs of circle (x_1,x_2), (x_2,x_3), (x_3,x_1). These arcs have respective radii h_{12}, h_{23}, h_{31} and respective angles b_{12}, b_{23}, b_{31}, each of these angles being in $[0;\pi]$. The trihedron intersects each of the planes respectively tangent to the sphere at x_1, x_2, x_3, thus defining the respective angles a_1, a_2, a_3, each of these angles being in $[0;\pi]$. We define c_{12}, c_{23}, c_{31} as the projections of c on the planes containing the respective triplets (x_1,z,x_2), (x_2,z,x_3), (x_3,z,x_1). We also define the angles associated to the three lens: $\theta_{ij} = \widehat{x_i,c,c_{ij}} = \widehat{x_j,c,c_{ij}}$, $(i,j)=(1,2)$ or $(i,j)=(2,3)$ or $(i,j)=(3,1)$, such that $\cos\theta_{ij}$ is positive when the vector $c_{ij}-c$ of origin c has the same sense than the direct normal to the plane of the oriented arc (x_i,x_j), and $\cos\theta_{ij}$ is negative when $c_{ij}-c$ has a sense opposite to this normal. We have also $\sin\theta_{ij} = h_{ij}/R$. The sphere has a constant Gaussian curvature and each arc of circle has a constant geodesic curvature. Thus, the Gauss–Bonnet theorem [26, 52] leads to a simple expression of S_{st} in Eq. (4.22), in which the first term in parenthesis is the spherical excess:

$$\frac{S_{st}}{R^2} = (a_1 + a_2 + a_3 - \pi) - (b_{12}\cos\theta_{12} + b_{23}\cos\theta_{23} + b_{31}\cos\theta_{31}). \tag{4.22}$$

V_{zx} being the signed volume of the oriented tetrahedron $(x_1 - z, x_2 - z, x_3 - z)$ and V_{cx} being the signed volume of the oriented tetrahedron $(x_1 - c, x_2 - c, x_3 - c)$, the volume V_{st} is given below [37]:

$$\begin{aligned} V_{st} = \frac{R^3}{6} \big[&\cos\theta_{12} \sin^2\theta_{12} (\sin b_{12} - b_{12}) \\ &+ \cos\theta_{23} \sin^2\theta_{23} (\sin b_{23} - b_{23}) \\ &+ \cos\theta_{31} \sin^2\theta_{31} (\sin b_{31} - b_{31}) \big] + V_{zx} - V_{cx} + \frac{S_{st} R}{3}. \end{aligned} \tag{4.23}$$

When z lies at c, we retrieve the expression given by Girard's theorem [48]: $\frac{S_{st}}{R^2}$ is the spherical excess and $V_{st} = \frac{S_{st} R}{3}$.

Remark: rather than looking for the validity of Eq. (4.23) from integrating S_{st} as stated in [37], we give a hint of proof as follows. We define the point x_0 at the intersection of the half line of origin c passing through z with the boundary of the sphere, and we add the three signed contributions to V_{st} due to the trihedra $\{z \to x_1, z \to x_2, z \to x_0\}$ and $\{z \to x_2, z \to x_3, z \to x_0\}$ and $\{z \to x_3, z \to x_1, z \to x_0\}$, a contribution being negative when the bounding arcs are not oriented in the conventional sense. For each trihedra, say, $\{z \to x_1, z \to x_2, z \to x_0\}$, the volume of the intersection with the sphere is $V_{sc012} - V_{cz12} - V_{c12}$, in which V_{sc012} is the volume of the domain bounded by $c - x_0$, $c - x_1$, $c - x_2$ and by the spherical triangle (x_0, x_1, x_2) intercepted by the trihedron $\{z \to x_1, z \to x_2, z \to x_0\}$ and of area computable by Eq (4.22). Despite that this domain is not bounded by a trihedron, V_{sc012} is computable by trivial integration in respect to the radius of the sphere. V_{cz12} is the volume of the tetrahedron (c, z, x_1, x_2). V_{c12} is the volume of the portion of the cone of origin c with height $R\cos\theta_{12}$ and of basis the circular segment of area $(b_{12} - \sin b_{12})(R \sin\theta_{12})^2/2$, i.e., $V_{c12} = \cos\theta_{12} \sin^2\theta_{12} (b_{12} - \sin b_{12}) R^3/6$. The rest of the calculation is easy.

The case of the six trihedra listed at the end of Sect. 4.2.4 is of interest. It is such that one of the arcs, say, (x_2, x_3), lies on a great circle of the sphere: z, x_2, x_3, c, c_{12}, c_{31}, are coplanar, and c_{23} coincides with c, then $a_2 = \pi/2$, $a_3 = \pi/2$, and $\theta_{23} = \pi/2$.

Grouping each trihedra with its symmetric image through the plane of the great circle let us to the expressions of the volume V_{sd} of the intersection of a sphere and a dihedron and for the surface S_{sd} of the associated portion of spherical area. Keeping the notations used in Eqs. (4.22) and (4.23):

$$\frac{S_{sd}}{R^2} = 2a_1 - 2(b_{12}\cos\theta_{12} + b_{31}\cos\theta_{31}), \tag{4.24}$$

$$\begin{aligned} V_{sd} = \frac{R^3}{3} \big[&\cos\theta_{12} \sin^2\theta_{12} (\sin b_{12} - b_{12}) \\ &+ \cos\theta_{31} \sin^2\theta_{31} (\sin b_{31} - b_{31}) \big] + 2(V_{zx} - V_{cx}) + \frac{S_{sd} R}{3} \Bigg]. \end{aligned} \tag{4.25}$$

Care: in Eqs. (4.24) and (4.25), b_{12} and b_{31} are the angles of the half arcs (not the full arcs) bounding the intersection of the sphere with the dihedron. It is also recalled that the arcs must be correctly oriented and that $\cos\theta_{12}$ and $\cos\theta_{31}$ can be negative.

When z is outside the sphere, the intersection with a dihedron reduces to simpler cases such as a sphere minus two lens, and the intersection with a trihedron can be reduced to intersections with appropriate dihedra or trihedra for which Eqs. (4.22)–(4.25) can be used. More generally we can extend volumes and surfaces computations to the intersections of a sphere with a tetrahedron, a convex polyhedron, and with any union of convex polyhedra. These computations are based on Eqs. (4.22)–(4.25) but are not needed in the framework of this chapter.

4.2.7 Intersections of Order 5 and Higher

By iterating Eqs. (4.12) and (4.13) until order n, the volume and the surface of the union of the n spheres can be expressed from the inclusion–exclusion principle as follows:

$$V = \sum_{1\le i\le n} V_i - \sum_{1\le i_1<i_2\le n} V_{i_1 i_2} + \sum_{1\le i_1<i_2<i_3\le n} V_{i_1 i_2 i_3} + \cdots + (-1)^{n-1} V_{i_1 i_2 \cdots i_n}, \quad (4.26)$$

$$S = \sum_{1\le i\le n} S_i - \sum_{1\le i_1<i_2\le n} S_{i_1 i_2} + \sum_{1\le i_1<i_2<i_3\le n} S_{i_1 i_2 i_3} + \cdots + (-1)^{n-1} S_{i_1 i_2 \cdots i_n}. \quad (4.27)$$

Setting $d = 3$ and $n \ge 5$, the existence of intersections of order n is deduced from Helly's theorem [14]. It means that the intersection of five spheres is not empty if and only if each of the five subsets of four spheres gives rise to a non-empty intersection. If $n \ge 6$, the intersection of six spheres is not empty if and only if each of the six subsets of five spheres gives rise to a nonempty intersection.

For practical computations, we need Theorem 4.5:

Theorem 4.5. *When $n \ge 5$ spheres in E^3 have a common non-empty intersection, there are m (with $1 \le m \le 3$) of these spheres such that their union J contains the intersection I of the $n - m$ remaining spheres.*

Proof. Assume initially that $n = 5$ spheres have a common non-empty intersection. From Helly's theorem, each of the five subsets of four spheres gives rise to a nonempty intersection. If one of these subsets of four spheres is such that the union of $m = 1, 2$, or three spheres contains the intersection of the $4 - m$ remaining spheres, the union of these m spheres contains the intersection of the $5 - m$ remaining spheres and the theorem stands. As stated in Sect. 4.2.5, a set of four spheres giving rise to a nonempty intersection which is not in one of these latter configurations is in the general configuration.

Now we need to prove the theorem when the five subsets of four spheres are in the case of a general configuration. For this latter, the four contact point pairs between three spheres are such that one of these contact points lies inside the fourth sphere

Theorem 1.1.1 *For any two distinct points p and q there exists a point r which lies between p and q, i.e. the line segment $\overline{pq}$ is not empty.*

Proof Let p and q be two points. By axiom I_4 there exists a point s that does not lie on the straight line $L(p,q)$. By axiom A_3 there is a point t such that s lies between p and t. Another application of axiom A_3 gives a point u such that q lies between t and u. The straight line $L := L(s,u)$ intersects the line segment $\overline{pt}$ at s.

The point t does not lie on the straight line $L(p,q)$, since otherwise s would by axiom A_1 also lie on that straight line, contradicting the choice of s. We can therefore apply axiom A_5 to the straight line L and the three points p, q and t. As L intersects the line segment $\overline{pt}$, L must by axiom A_5 also intersect one of the two line segments $\overline{pq}$ or $\overline{tq}$, unless it contains one of the three points p, q or t.

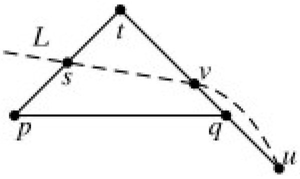
First case L contains p or t.

Then L agrees with the straight line $L(p,t)$ by axiom I_2. Hence u lies on $L(p,t)$ and axiom A_1 implies that q lies on $L(p,t)$ as well. Hence p, q and t do lie on a straight line, a contradiction.

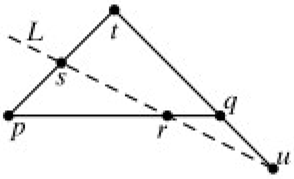
Second case L contains q.

Several applications of axiom I_2 show that the points s, u, q, t and p lie on a straight line, a contradiction.

Third case L intersects the line segment $\overline{tq}$ at a point v.



Then L and $L(t,q)$ have the two points u and v in common. If $u = v$, then u would lie between t and q while q lies between t and u, a contradiction to axiom A_4. Thus L and $L(t,q)$ have two distinct points in common, and axiom I_2 implies that $L = L(t,q)$. But then both s and p lie on L, i.e. p, q and t lie on a straight line, a contradiction.



Thus L and $\overline{pq}$ must intersect at a point r. In particular, $\overline{pq}$ cannot be empty. □

Exercise 1.1 Let p, q, r and s be points on a straight line. Show that if q lies between p and s and if additionally r lies between q and s, then r lies between p and s as well.

Using this exercise and theorem 1.1.1, it is now easy to solve the following exercise.

Exercise 1.2 Show the following: there is an infinite number of distinct points between two points.

Definition 1.1.2 Let L be a straight line, $p \in L$. Let q and r be two points on L, neither of which is p. We say that q and r ***lie on the same side of the point*** p if p does not lie between q and r.

Exercise 1.3 Let L be a straight line and let $p \in L$ be a point on L. Show that the relation "q_1 lies on the same side of p as q_2" defines an equivalence relation on the set $\{q \in L \mid q \neq p\}$.

An equivalence class of points on L that do not equal p can then be referred to as a ***side of*** p ***on*** L.

Exercise 1.4 Show that there are exactly two sides of p on L.

Definition 1.1.3 Let L be a straight line and let p and q be two points that do not lie on L. We say that p and q ***lie on the same side of a straight line*** L if the line segment $\overline{pq}$ does not intersect the straight line L.

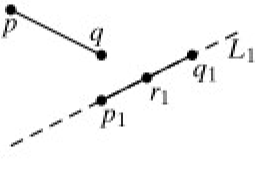
Exercise 1.5 Let L be a straight line. Show that the relation "q_1 lies on the same side of L as q_2" defines an equivalence relation on the set $\{q \mid q \notin L\}$.

Again we can call an equivalence class of points not on L a ***side of*** L.

Exercise 1.6 Show that there are exactly two sides of L.

Congruence axioms To formulate the third group of axioms, the congruence axioms, we need in addition to the previous notions that for every pair $(\overline{pq}, \overline{p_1q_1})$ of line segments the formal statement "$\overline{pq}$ is congruent to $\overline{p_1q_1}$" is either true or false.

Axiom K_1 (reproduction of lengths) *Let $\overline{pq}$ be a line segment, let L_1 be a straight line, let $p_1, r_1 \in L_1$, $r_1 \neq p_1$. Then there is a point $q_1 \in L_1$ on the same side of p_1 as r_1 such that $\overline{pq}$ is congruent to $\overline{p_1q_1}$.*



In this axiom only the existence of a congruent line segment is required. Its uniqueness needs to be proved later with the aid of other axioms.

Axiom K_2 *If the line segments $\overline{p_1q_1}$ and $\overline{p_2q_2}$ are both congruent to the line segment $\overline{pq}$, then $\overline{p_1q_1}$ is congruent to $\overline{p_2q_2}$ as well.*

Four more congruence axioms will follow. We can nevertheless already prove a first implication.

Lemma 1.1.4 *The congruence of line segments defines an equivalence relation on the set of line segments.*

Proof (a) Let $\overline{pq}$ be a line segment. We show that $\overline{pq}$ is congruent to itself. Let L be a straight line that contains p, $p \in L$. By axiom K_1 there exists a point r on L such that $\overline{pq}$ and $\overline{pr}$ are congruent. Then $\overline{p_1q_1} := \overline{p_2q_2} := \overline{pq}$ is congruent to $\overline{pr}$ and hence $\overline{pq}$ is by axiom K_2 congruent to itself.

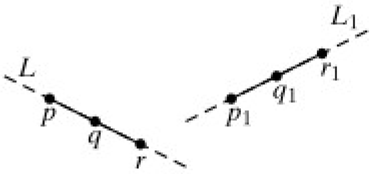
(b) (symmetry) Let $\overline{pq}$ be congruent to $\overline{p_1q_1}$. We show that then $\overline{p_1q_1}$ is congruent to $\overline{pq}$. It follows from (a) that $\overline{p_1q_1}$ is congruent to $\overline{p_1q_1}$. Axiom K_2 now gives that $\overline{p_1q_1}$ is congruent to $\overline{pq}$.

(c) (transitivity) If $\overline{p_1q_1}$ is congruent to $\overline{p_2q_2}$ and $\overline{p_2q_2}$ is congruent to $\overline{p_3q_3}$, then we need to show that $\overline{p_1q_1}$ is congruent to $\overline{p_3q_3}$. This follows directly from axiom K_2 together with (b). ☐

We will from now on sometimes denote "$\overline{p_1q_1}$ is congruent to $\overline{p_2q_2}$" by "$\overline{p_1q_1} \equiv \overline{p_2q_2}$".

Axiom K_3 (additivity of line segments) *Let L and L_1 be straight lines, let $p, q, r \in L$ be three pairwise distinct points on L and $p_1, q_1, r_1 \in L_1$ likewise on L_1. Assume that the line segments $\overline{pq}$ and $\overline{qr}$ do not have any common points, $\overline{pq} \cap \overline{qr} = \emptyset$. Analogously let $\overline{p_1q_1} \cap \overline{q_1r_1} = \emptyset$.*

If now $\overline{pq} \equiv \overline{p_1q_1}$ and $\overline{qr} \equiv \overline{q_1r_1}$, then $\overline{pr} \equiv \overline{p_1r_1}$.



We need the concept of the *angle* for the formulation of the three other congruence axioms.

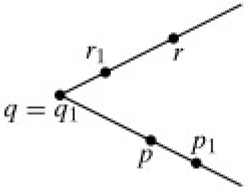
Definition 1.1.5 An ***angle*** is an equivalence class of triples of points p, q and r that do not lie on a straight line, where two triples (p, q, r) and (p_1, q_1, r_1) are equivalent if

(i) $q = q_1$,
(ii) $L(p, q) = L(p_1, q)$ and p and p_1 lie on the same side of q,
(iii) $L(r, q) = L(r_1, q)$ and r and r_1 lie on the same side of q,

or if

(i) $q = q_1$,
(ii) $L(p, q) = L(r_1, q)$ and p and r_1 lie on the same side of q,
(iii) $L(r, q) = L(p_1, q)$ and r and p_1 lie on the same side of q.

For the equivalence class of (p, q, r) we write $\angle(p, q, r)$. The point q is then called the ***vertex*** of the angle $\angle(p, q, r)$.

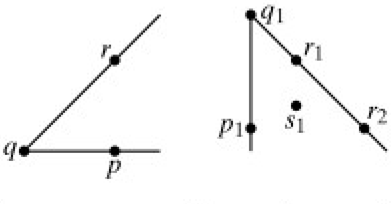


We now additionally require that for any two angles $\angle(p, q, r)$ and $\angle(p_1, q_1, r_1)$ the formal statement "$\angle(p, q, r)$ is congruent to $\angle(p_1, q_1, r_1)$" is either true or false. Again, we write "$\angle(p, q, r) \equiv \angle(p_1, q_1, r_1)$" if $\angle(p, q, r)$ is congruent to $\angle(p_1, q_1, r_1)$.

Axiom K_4 *The congruence of angles induces an equivalence relation on the set of angles.*

Axiom K_5 (reproduction of angles) *Let p, q, r be points that do not lie on a straight line, and let p_1, q_1, s_1 be another set of points that do not lie on a straight line. Then there exists a point r_1 on the same side of $L(p_1, q_1)$ as s_1 such that the angle $\angle(p_1, q_1, r_1)$ is congruent to the angle $\angle(p, q, r)$.*

If r_2 is another point with the same properties as r_1, i.e. r_2 also lies on the same side of $L(p_1, q_1)$ as s_1 and if $\angle(p_1, q_1, r_2) \equiv \angle(p, q, r)$, then $\angle(p_1, q_1, r_1) = \angle(p_1, q_1, r_2)$.

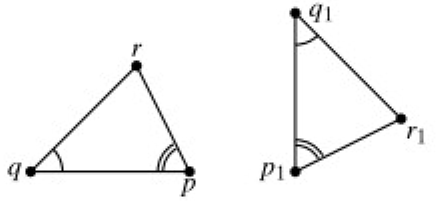


Axiom K_5 says that we can reproduce a given angle in a unique way if we are given the vertex, one line adjacent to the angle and the side of the other line next to the angle.

The last congruence axiom relates the congruence of line segments to that of angles. Until now the two notions of congruence existed entirely separately.

Axiom K_6 *Let* (p,q,r) *be a triple of points that do not lie on a straight line and* (p_1,q_1,r_1) *likewise. If* $\overline{pq} \equiv \overline{p_1q_1}$, $\overline{pr} \equiv \overline{p_1r_1}$ *and* $\angle(q,p,r) \equiv \angle(q_1,p_1,r_1)$, *then*

$$\angle(p,q,r) \equiv \angle(p_1,q_1,r_1).$$

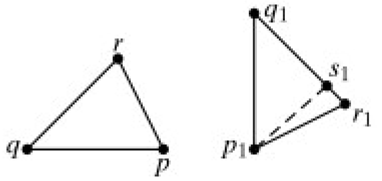


Let us make some inferences using the axioms introduced so far. We will first extend the statement of the last axiom.

Theorem 1.1.6 *Let* (p,q,r) *be a triple of points that do not lie on a straight line,* (p_1,q_1,r_1) *likewise. If* $\overline{pq} \equiv \overline{p_1q_1}$, $\overline{pr} \equiv \overline{p_1r_1}$ *and* $\angle(q,p,r) \equiv \angle(q_1,p_1,r_1)$, *then*

$$\angle(p,q,r) \equiv \angle(p_1,q_1,r_1), \qquad \angle(p,r,q) \equiv \angle(p_1,r_1,q_1), \qquad \overline{qr} \equiv \overline{q_1r_1}.$$

Proof The angle congruences follow directly from axiom K_6, in the second case after renaming the variables. It remains to show that $\overline{qr} \equiv \overline{q_1r_1}$. By axiom K_1 we can find a point s_1 on the straight line $L(q_1,r_1)$ which is on the same side as r_1 and satisfies $\overline{qr} \equiv \overline{q_1s_1}$.



We apply axiom K_6 to (p,q,r) and (p_1,q_1,s_1) and conclude that

$$\angle(q,p,r) \equiv \angle(q_1,p_1,s_1).$$

On the other hand we have $\angle(q,p,r) \equiv \angle(q_1,p_1,r_1)$, and by the uniqueness from axiom[1] K_5

---

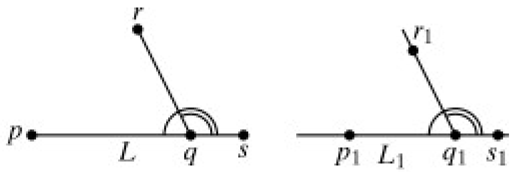
[1] For an application of the uniqueness statement from axiom K_5 it must be ensured that r_1 and s_1 lie on the same side of $L(p_1,q_1)$. This is left as an exercise for the reader.

$$\angle(q_1, p_1, s_1) = \angle(q_1, p_1, r_1).$$

If we now had $r_1 \neq s_1$, then we would conclude that p_1 and q_1 both lie on the straight line $L(r_1, s_1)$, i.e. p_1, q_1 and r_1 would lie on a straight line, which contradicts the assumption.

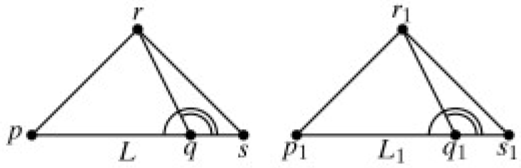
Thus $r_1 = s_1$ and hence $\overline{qr} \equiv \overline{q_1 r_1}$. ☐

Theorem 1.1.7 (Congruence of adjacent angles) *Suppose that the pairwise distinct points p, q and s lie on a straight line L, while $r \notin L$. Analogously, let $p_1, q_1, s_1 \in L_1$ be pairwise distinct, $r_1 \notin L_1$. If $\angle(p,q,r)$ and $\angle(p_1,q_1,r_1)$ are congruent, then the same is true for $\angle(s,q,r)$ and $\angle(s_1,q_1,r_1)$.*



The angle $\angle(s,q,r)$ is sometimes called the ***adjacent angle*** of $\angle(p,q,r)$. The theorem thus says that adjacent angles of congruent angles are congruent as well.

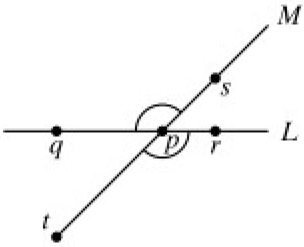
Proof The points p_1, r_1 and s_1 can by axiom K_1 be assumed to have been chosen in such a way that $\overline{pq} \equiv \overline{p_1 q_1}$, $\overline{rq} \equiv \overline{r_1 q_1}$ and $\overline{sq} \equiv \overline{s_1 q_1}$.



From theorem 1.1.6, applied to (p,q,r) and (p_1,q_1,r_1), it follows that $\overline{pr} \equiv \overline{p_1 r_1}$. By axiom K_3 we then have $\overline{ps} \equiv \overline{p_1 s_1}$. Applying theorem 1.1.6 once again, this time to (r,p,s) and (r_1,p_1,s_1), we obtain $\overline{rs} \equiv \overline{r_1 s_1}$ and $\angle(q,s,r) \equiv \angle(q_1,s_1,r_1)$. Axiom K_6 then says for (q,s,r) and (q_1,s_1,r_1) that $\angle(s,q,r) \equiv \angle(s_1,q_1,r_1)$. ☐

Theorem 1.1.8 (Congruence of vertical angles) *Let L and M be two distinct straight lines that intersect at p. Let $r, q \in L$ lie on two distinct sides of p and let $s, t \in M$ lie on two distinct sides of p as well. Then*

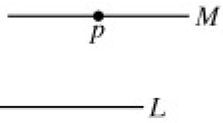
$$\angle(q,p,s) \equiv \angle(r,p,t).$$



Proof Both $\angle(q,p,s)$ and $\angle(r,p,t)$, are adjacent angles of $\angle(q,p,t)$. The angle $\angle(q,p,t)$ is congruent to itself by axiom K_4. The claim therefore follows by theorem 1.1.7. ☐

After these preparations we now come to the first truly interesting geometric theorem.

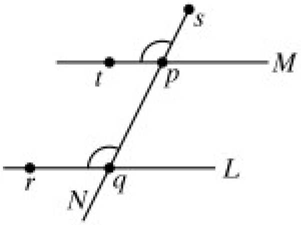
Theorem 1.1.9 (Existence of a parallel) *Let L be a straight line, p a point, $p \notin L$. There then exists a straight line M that contains p and that does not intersect L.*



We then say that M is a ***parallel*** to L through p. The theorem says that such parallels always exist.

Proof Let L be a straight line and p a point that does not lie on L. We will first construct the line M and then show that it has the desired properties.

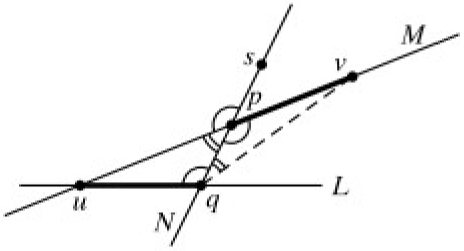
For the construction we choose a point $q \in L$ and add the straight line $N := L(p,q)$. We choose another point $r \in L$, $r \neq q$. Then $r \notin N$, since otherwise $p \in L(p,q) = L(q,r) = L$. We reproduce angle $\angle(r,q,p)$ as in axiom K_5 on the straight line N at the point p, i.e. we find points $s \in N$ and $t \notin N$ on the same side of N as r, such that the angle $\angle(t,p,s)$ is congruent to the angle $\angle(r,q,p)$. We now set $M := L(p,t)$.



It remains to show that L and M do not intersect. Suppose that L and M did intersect at a point u. We restrict ourselves to the case that u lies on the same side of N as r and t. The other case is dealt with in a similar way.

We reproduce the line segment $\overline{uq}$ on the straight line M as in axiom K_1, beginning at the point p, and we do *not* do this on the same side as u. This means that $\overline{uq} \equiv \overline{pv}$, with a point $v \in M$ such that p lies between u and v.

The angles $\angle(u,p,s)$ and $\angle(q,p,v)$ are congruent by theorem 1.1.8. Hence the angles $\angle(u,q,p)$ and $\angle(q,p,v)$ are congruent as well. We apply axiom K_6 to (u,q,p) and (v,p,q), and see that $\angle(q,p,u) \equiv \angle(p,q,v)$.



But $\angle(q,p,u)$ is an adjacent angle of $\angle(u,p,s)$, so by theorem 1.1.7 and by the uniqueness of the reproduction of angles $\angle(p,q,v)$ must be an adjacent angle of $\angle(u,q,p)$. Hence v lies on the straight line L, and thus the same is true for p, which contradicts the assumption. ☐

Parallel axiom We have seen that the existence of parallels can be proved using the axioms introduced so far. What about their uniqueness? This is the subject of the parallel axiom.

AXIOM P (parallel axiom) *Let L be a straight line, p a point, $p \notin L$. Then there is at most one straight line that contains p and does not intersect L.*

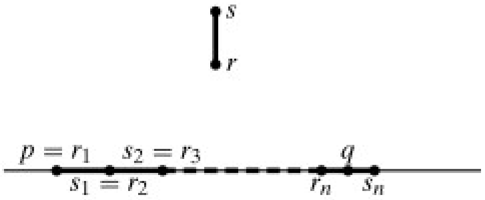
There has been controversy about the necessity of this axiom for thousands of years. Many mathematicians believed that uniqueness could, as existence, be deduced from the other axioms. There were many proof attempts. Carl Friedrich Gauss (1777–1855) was probably the first person to truly believe in the independence of the parallel axiom. However, he never published his views about it. The debate was ended by the Russian Nikolai Iwanowitsch Lobatschewski (1792–1856) and by the Hungarian Janos Bolyai (1802–1860), who, independently of each other, found a geometry that satisfies all axioms except for the parallel axiom. Hence the parallel axiom cannot be derived from the other axioms. Bolyai's father, a teacher of mathematics himself, was so worried about his son's result that he wrote a letter to Gauss, asking him for his opinion. In his answer Gauss was enthusiastic about the work of the younger Bolyai, but added the remark that he could not praise him, since this would be self-praise as he, Gauss, had known this for many years. Janos Bolyai never again published work on mathematics.

The afore-mentioned geometry is hyperbolic geometry, also known as non-Euclidean geometry. We will cover it in more detail later.

,9 J))));

Completeness axioms When real numbers are introduced in analysis, one becomes acquainted with the completeness axioms, which distinguish the real numbers from the rational numbers and other ordered number fields. To determine the Euclidean geometry completely, we need the appropriate axioms.

Axiom V_1 (Archimedes's axiom) *Let $\overline{pq}$ and $\overline{rs}$ be two line segments. Then there exists a natural number n such that the line segment $\overline{r_1 s_n}$, which results from the n-fold reproduction of the line segment $\overline{rs}$ on the straight line $L(p,q)$, starting at p in direction q, contains the line segment $\overline{pq}$.*



Before formulating the last axiom, we summarise those notions that we need for the axiomatic formulation of Euclidean geometry. We have

- a set $\mathscr{P}$, whose elements are called points,
- a set $\mathscr{G}$, whose elements we call straight lines,
- a relation $\in$ between $\mathscr{P}$ and $\mathscr{G}$,
- a three-figure relation “between” on $\mathscr{P}$,
- a relation $\equiv_1$ on the set of straight lines,
- a relation $\equiv_2$ on the set of angles.

One could now formally define a Euclidean geometry as a 6-tuple $(\mathscr{P}, \mathscr{G}, \in, \text{between}, \equiv_1, \equiv_2)$ that consists of such notions, and that satisfies axioms I_1–I_4, A_1–A_5, K_1–K_6, P, V_1 as well as V_2, which still is to be formulated.

An ***extension*** of our geometry is a second 6-tuple $(\mathscr{P}', \mathscr{G}', \in', \text{between}', \equiv_1', \equiv_2')$ such that $\mathscr{P} \subset \mathscr{P}'$, $\mathscr{G} \subset \mathscr{G}'$ and the relations $\in'$, between$'$, $\equiv_1'$ as well as $\equiv_2'$ agree with the corresponding relations $\in, \ldots$ after a restriction to $\mathscr{P}$ and $\mathscr{G}$.

Axiom V_2 (maximality) *Let $(\mathscr{P}', \mathscr{G}', \in', \text{between}', \equiv_1', \equiv_2')$ be an extension of our geometry. Then $\mathscr{P}' = \mathscr{P}$ and $\mathscr{G}' = \mathscr{G}$.*

Our geometry is therefore assumed to be non-extensible, i.e. maximal.

For a further discussion of axiomatic geometry the reader is referred to Hilbert's book [13]. Proofs of numerous geometric theorems, a discussion of the uniqueness of Euclidean geometry and of the necessity of Archimedes's axiom, straightedge-and-compass constructions and spatial Euclidean geometry can be found there. On a final note, some axioms can be weakened slightly, e.g. axioms K_4 and V_2.

1.2 The Cartesian model

While the axiomatic method ensures logical clarity in the structural layout of geometry, it is also annoyingly clumsy. The proofs of even relatively simple geometric facts can easily become quite laborious. In addition, dealing with geometric objects that are not composed of line segments, circular lines, and so forth is relatively involved.

We therefore now follow the ideas of the Frenchman René Descartes (1596–1650) and characterise points by coordinates, which give the positions of the points in the plane. This allows us to use methods from algebra and infinitesimal calculus in geometry, extending our mathematical toolkit considerably.

We hence make the definition

$$\mathscr{P} := \mathbb{R}^2.$$

Straight lines are defined as sets of points of the form

$$L = L_{p,v} := \{x \in \mathbb{R}^2 \mid x = p + t \cdot v,\ t \in \mathbb{R}\},$$

where $p, v \in \mathbb{R}^2$, $v \neq 0$, are fixed. The set of straight lines is then

$$\mathscr{G} := \{L_{p,v} \mid p, v \in \mathbb{R}^2, v \neq 0\}.$$

We say that a point p is ***contained*** in a straight line L if $p \in L$ in the set-theoretic sense.

Exercise 1.7 Verify the validity of axioms I_1–I_4.

A point $q \in \mathbb{R}^2$ lies ***between*** p and $r \in \mathbb{R}^2$, $p \neq r$, if there exists a $t \in (0,1)$ such that $q = t \cdot p + (1-t) \cdot r$.

Exercise 1.8 Show that axioms A_1–A_4 are valid.

It remains to define the congruence relations. This is done using a suitable group of maps, which acts on the set of points.

Definition 1.2.1 Let $A \in \mathrm{O}(n)$ be an orthogonal matrix, i.e. it satisfies $A \cdot A^\top = \mathrm{Id}$, where $A^\top$ is the transpose of A. Let $b \in \mathbb{R}^n$.

Then the map

$$F_{A,b} : \mathbb{R}^n \to \mathbb{R}^n, \qquad F_{A,b}(x) = Ax + b,$$

is called a ***Euclidean motion***. The vector b is sometimes called the ***translational part***. For a fixed dimension n, we call the set of all Euclidean motions,

$$\mathrm{E}(n) := \{F_{A,b} \mid A \in \mathrm{O}(n), b \in \mathbb{R}^n\},$$

the ***Euclidean motion group***.

Exercise 1.9 Show the following: composition of maps turns $\mathrm{E}(n)$ into a group with neutral element Id. Products and inverses are given by $F_{A,b} \circ F_{B,c} = F_{AB,Ac+b}$ and $F_{A,b}^{-1} = F_{A^{-1},-A^{-1}b}$ respectively.

Exercise 1.10 Show that axiom A_5 is valid.

Hint An application of a Euclidean motion maps the straight line L to the x-axis $L' = \{(x,0)^\top \mid x \in \mathbb{R}\}$. Then argue that two points $(x,y)^\top$ and $(x',y')^\top$ from $\mathbb{R}^2 - L'$ lie on the same side of L' if and only if y and y' are both positive or both negative.

Definition 1.2.2 Two line segments $\overline{pq}$ and $\overline{rs}$ are said to be ***congruent*** if there exists a Euclidean motion $F \in \mathrm{E}(2)$ such that

$$\overline{F(p)F(q)} = \overline{rs}.$$

Analogously, the angle $\angle(p,q,r)$ is ***congruent*** to $\angle(p_1,q_1,r_1)$ if there is an $F \in \mathrm{E}(2)$ such that

$$\angle(F(p),F(q),F(r)) = \angle(p_1,q_1,r_1).$$

Exercise 1.11 Show the validity of axioms K_1–K_6.

Exercise 1.12 Show the validity of the parallel axiom P.

Exercise 1.13 Show the validity of Archimedes's axiom V_1.

The proof of the maximality axiom V_2 requires more thought than those of the other axioms. We therefore want to show it here.

Theorem 1.2.3 *With the definitions made above the maximality axiom* V_2 *is valid.*

Proof Let $\mathscr{P}' \supset \mathscr{P}$ and $\mathscr{G}' \supset \mathscr{G}$ be respectively the set of points and the set of straight lines of an extension of our Cartesian model of Euclidean geometry. We will call the points from $\mathscr{P}$ *old points*, and those from $\mathscr{P}' - \mathscr{P}$ *new points*. We use analogous notation when dealing with straight lines. It needs to be shown that there cannot be new points and straight lines at all, $\mathscr{P} = \mathscr{P}'$ and $\mathscr{G} = \mathscr{G}'$.

The proof is accomplished in three steps. We first show that the old straight lines do not contain new points, then that there are no new points, and finally that there are no new straight lines.

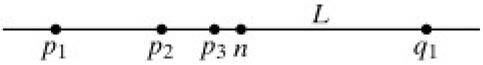
(a) *Old straight lines do not contain new points, i.e. for* $L \in \mathscr{G}$ *and* $p \in \mathscr{P}'$ *with* $p \in' L$ *we have* $p \in \mathscr{P}$.

One must not become confused at this point. According to our definition, old straight lines are sets of old points. In the *set-theoretic sense* old straight lines only contain old points anyway. Nevertheless, it is a priori possible that new points are contained in old straight lines for the extension $\in'$ of the set-theoretic inclusion $\in$. It now needs to be shown that this is not the case.

For this purpose let $L \in \mathscr{G}$ be an old straight line. Suppose that L contains a new point n. We choose an old point $p_1 \in L$. As L is of the form $L = L_{p,v}$, we can write $p_1 = p + t_1 v =: c(t_1)$, $t_1 \in \mathbb{R}$. If we reproduce the line segment $\overline{(0,0)^\top(0,1)^\top}$ sufficiently often on L, starting at p_1 in direction n, then we obtain by Archimedes's axiom a second point $q_1 \in L$ such that n lies between p_1 and q_1. Reproducing the line segment $\overline{(0,0)^\top(0,1)^\top}$ on an old straight line starting at an old point always gives another old point. Thus q_1 is an old point. We write $q_1 = c(s_1)$, $s_1 \in \mathbb{R}$. Without loss of generality let $t_1 < s_1$.

We now decompose the real numbers into two disjoint subsets, $\mathbb{R} = T \sqcup S$, where $T = \{t \in \mathbb{R} \mid c(t) \text{ lies on the same side of } n \text{ as } c(t_1)\}$ and $S = \{t \in \mathbb{R} \mid c(t) \text{ lies on the same side of } n \text{ as } c(s_1)\}$. This decomposition of the real numbers constitutes a Dedekind cut. By the completeness of $\mathbb{R}$ either the subset T must have a maximum or S a minimum. We deal with the case that T has a maximum t_2. The other case can be treated analogously.

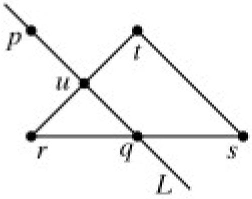
We set $p_2 := c(t_2)$. As $t_2 \in T$, the points p_1 and p_2 must lie on the same side of n. By Archimedes's axiom, there is a natural number k such that k-fold reproduction of the line segment $\overline{p_2 n}$ on L from p_2 in direction q_1 contains the line segment $\overline{p_2 q_1}$. We set $p_3 := c(t_3)$ with $t_3 = t_2 + (s_1 - t_2)/k$. Then the line segment $\overline{p_2 p_3}$ has the property that its k-fold reproduction on L from p_2 in direction q_1 gives the line segment $\overline{p_2 q_1}$.



As the line segment $\overline{p_2 q_1}$ is contained in the k-fold reproduced line segment $\overline{p_2 n}$, the line segment $\overline{p_2 p_3}$ must be contained in $\overline{p_2 n}$. Thus p_3 lies between p_2 and n. It follows that $t_3 \in T$ and $t_3 > t_2$. This contradicts the maximality of t_2.

(b) *There are no new points, i.e.* $\mathscr{P} = \mathscr{P}'$.

Let $p \in \mathscr{P}'$ be a point. We choose an old point $q \in \mathscr{P}$ and consider the straight line L through p and q. We now choose three old points $r, s, t \in \mathscr{P}$ that do not lie on a straight line and none of which lies on L, such that L and the line segment $\overline{rs}$ intersect at q.



It follows from axiom A_5 that L intersects the line segment $\overline{rt}$ or $\overline{ts}$ at a point u. As the two old straight lines $L(r,t)$ and $L(s,t)$ do not contain any new points by (a), u must be a new point. Thus $L = L(u,q)$ is an old straight line and contains, again by (a), no new points. Hence p is an old point, $p \in \mathscr{P}$.

(c) *There are no new straight lines, i.e.* $\mathscr{G} = \mathscr{G}'$.

Let $L \in \mathscr{G}'$ be a straight line. It follows from axiom I_3 that L contains two distinct points p and q. They must be old points by (b). Hence $L = L(p,q)$ is an old straight line, $L \in \mathscr{G}$. $\square$

Exercise 1.14 Give another proof for part (a) of theorem 1.2.3 by considering Cauchy sequences instead of Dedekind cuts.

The axioms of Euclidean plane geometry are thus valid for the Cartesian model. In particular, we see that the axioms are *consistent*.

Doing geometry in the Cartesian model has the advantage that we now have the whole mathematical machinery of differential and integral calculus to hand. This makes the treatment of Euclidean trigonometry relatively easy.

We will as of now use angle brackets to denote the standard scalar product on $\mathbb{R}^n$:

$$\langle x, y\rangle = \sum_{i=1}^{n} x^i y^i$$

for $x = (x^1, \dots, x^n)^\top, y = (y^1, \dots, y^n)^\top \in \mathbb{R}^n$.

If x, y and z are three points in $\mathbb{R}^2$ which do not lie on a straight line, then $|\langle y - x, z - x\rangle| \leq \|y - x\| \cdot \|z - x\|$ by the Cauchy–Schwarz inequality. Hence $|\langle y - x, z - x\rangle/(\|y - x\| \cdot \|z - x\|)| \leq 1$. Since $\cos : [0,\pi] \to [-1,1]$ is bijective we can define their ***interior angle*** as the unique number $\gamma \in [0,\pi]$ such that $\cos(\gamma) = \langle y - x, z - x\rangle/(\|y - x\| \cdot \|z - x\|)$.

Exercise 1.15 Show that if x, y, z, and x', y', z' represent the same angle in the sense of definition 1.1.5, $\angle(y,x,z) = \angle(y',x',z')$, then they have the same interior angle, $\gamma = \gamma'$.

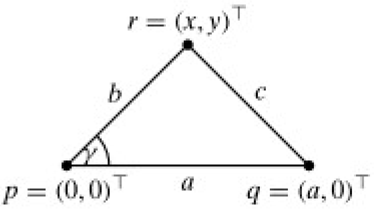
Exercise 1.16 Show that two angles are congruent if and only if they have the same interior angle.

This is analogous to the fact that two line segments are congruent if and only if they have equal length.

Theorem 1.2.4 (cosine rule for Euclidean geometry) *Let* $p, q, r \in \mathbb{R}^2$. *Let* $a = \|p - q\|$, $b = \|p - r\|$ *and* $c = \|q - r\|$ *be the sides of a triangle with vertices* p, q *and* r. *Let* γ *be the interior angle at the vertex* p. *Then*

$$c^2 = a^2 + b^2 - 2ab\cos(\gamma).$$

Proof Euclidean motions do not change the side and angle ratios. We can therefore after the application of a suitable Euclidean motion assume that $p = (0,0)^\top$, $q = (a,0)^\top$ and $r = (x,y)^\top$.



Hence

$$c^2 = (x-a)^2 + y^2 = a^2 - 2ax + x^2 + y^2 = a^2 + b^2 - 2ax.$$

Further

$$\cos(\gamma) = \frac{\langle q, r\rangle}{ab} = \frac{xa + y \cdot 0}{ab} = \frac{ax}{ab}$$

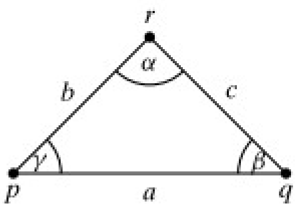
and thus $ax = ab\cos(\gamma)$. The claim follows. □

Corollary 1.2.5 (Pythagoras's theorem) *Using the notation from theorem 1.2.4 and letting the angle be a right angle,* $\gamma = \pi/2$, *the following equality holds:*

$$a^2 + b^2 = c^2.$$ □

Theorem 1.2.6 (sine rule for Euclidean geometry) *If* β *denotes the interior angle at vertex* q *and* α *the one at vertex* r, *then the following equality holds:*

$$\frac{a}{b} = \frac{\sin(\alpha)}{\sin(\beta)}.$$



Proof By the cosine rule the angle at vertex r satisfies

$$-2bc\cos(\alpha) = a^2 - (b^2 + c^2)$$

and hence

$$4b^2c^2\cos^2(\alpha) = \left(-a^2 + b^2 + c^2\right)^2 .$$

Analogously,

$$4a^2c^2\cos^2(\beta) = \left(a^2 - b^2 + c^2\right)^2 .$$

We therefore obtain

$$\begin{aligned}\frac{\sin^2(\alpha)}{\sin^2(\beta)} &= \frac{4a^2b^2c^2\left(1-\cos^2(\alpha)\right)}{4a^2b^2c^2\left(1-\cos^2(\beta)\right)} \\ &= \frac{4a^2b^2c^2 - a^2\left(-a^2+b^2+c^2\right)^2}{4a^2b^2c^2 - b^2\left(a^2-b^2+c^2\right)^2} \\ &= \frac{a^2}{b^2}\cdot\frac{4b^2c^2 - \left(a^4+b^4+c^4-2a^2b^2-2a^2c^2+2b^2c^2\right)}{4a^2c^2 - \left(a^4+b^4+c^4-2a^2b^2+2a^2c^2-2b^2c^2\right)} \\ &= \frac{a^2}{b^2}.\end{aligned}$$

□

Theorem 1.2.7 (angle sum in the Euclidean triangle) *The sum of the interior angles in the Euclidean triangle satisfies*

$$\alpha + \beta + \gamma = \pi .$$

Proof (a) We first prove the statement for right-angle triangles. Let $\gamma = \pi/2$. Then

$$\sin(\alpha + \beta + \pi/2) = \cos(\alpha + \beta) = \cos(\alpha)\cos(\beta) - \sin(\alpha)\sin(\beta). \tag{1.1}$$

Using the cosine rule 1.2.4 and Pythagoras's theorem we obtain

$$\begin{aligned}\cos(\alpha)\cos(\beta) &= \frac{-a^2+b^2+c^2}{2bc}\cdot\frac{a^2-b^2+c^2}{2ac}\\ &= \frac{2b^2\cdot 2a^2}{4abc^2}\\ &= \frac{ab}{c^2}.\end{aligned} \tag{1.2}$$

The sine rule 1.2.6 together with the cosine rule and Pythagoras's theorem gives

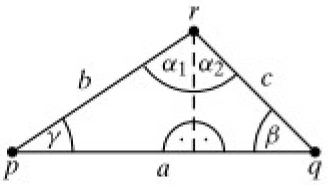
$$\begin{aligned}\sin(\alpha)\sin(\beta) &= \frac{b}{a}\sin^2(\alpha)\\ &= \frac{b}{a}\cdot\Big(1-\cos^2(\alpha)\Big)\\ &= \frac{b}{a}\cdot\left(1-\frac{\left(-a^2+b^2+c^2\right)^2}{4b^2c^2}\right)\\ &= \frac{b}{a}\cdot\left(1-\frac{4b^4}{4b^2c^2}\right)\\ &= \frac{b}{a}\cdot\frac{c^2-b^2}{c^2}\\ &= \frac{ab}{c^2}.\end{aligned} \tag{1.3}$$

Substituting (1.2) and (1.3) into (1.1), we obtain $\sin(\alpha+\beta+\pi/2)=0$, i.e. $\alpha+\beta+\pi/2$ is an integral multiple of π,

$$\alpha+\beta+\pi/2 = k\cdot\pi,$$

$k \in \mathbb{Z}$. As all angles in a right-angle triangle are > 0 and $\leq \pi/2$, we have $\pi/2 < \alpha+\beta+\pi/2 < 3\pi/2$ and thus $k=1$. It follows that $\alpha+\beta+\pi/2=\pi$, which proves the claim for right-angle triangles.

(b) In a general triangle let a be the longest side and r the vertex opposite to it. We drop a perpendicular from r to a and thus divide the triangle into two right-angle triangles.



We know from part (a) of this proof that in right-angle triangles $\alpha_1 + \gamma + \pi/2 = \pi$ and $\alpha_2 + \beta + \pi/2 = \pi$. Addition of those two equations gives $\alpha + \beta + \gamma = \pi$. □

Exercise 1.17 Prove the *half-angle theorem of Euclidean geometry*:

$$\tan^2\left(\frac{\alpha}{2}\right) = \frac{(a-b+c)(a+b-c)}{(a+b+c)(-a+b+c)}.$$

Hint Check and use the formula $\tan^2(t) = (1-\cos(2t))/(1+\cos(2t))$.

For comparison, we conclude this section by looking at another important classical geometry, i.e. ***spherical geometry***. The points of this geometry are not in the plane, but on the surface of a sphere. We set

$$\mathscr{P} := S^2 := \{(x,y,z)^\top \in \mathbb{R}^3 \mid x^2+y^2+z^2=1\}.$$

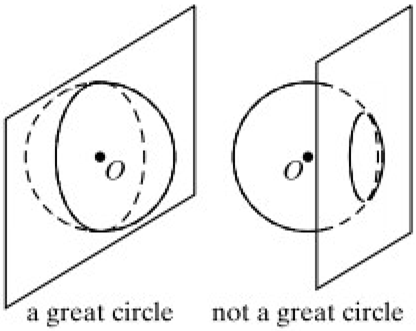
We call S^2 the ***two-dimensional sphere***.

This raises the question of what the "straight lines" are in this geometry. The straight lines in the plane can be characterised by the fact that each of them is the shortest curve connecting any two of its points. On the sphere the great circles have this property. A ***great circle*** is the subset of S^2 in which a two-dimensional vector subspace of $\mathbb{R}^3$, i.e. a plane that passes through 0, intersects the surface of the sphere.

We therefore set

$$\mathscr{G} := \{S^2 \cap E \mid E \text{ is a two-dimensional vector subspace of } \mathbb{R}^3\}.$$

The incidence relation $\in$ must here be interpreted in the set-theoretic sense again.



a great circle not a great circle

Exercise 1.18 Which of the axioms I_1–I_4 are valid?

Given three points on a great circle, it is not possible to say in a meaningful way which of them lies between the two others. Let us try with the following definition: if $p, q, r \in S^2$, then q lies ***between*** p and r if and only if p, q and r are three pairwise distinct points on a great circle.

Exercise 1.19 What is a line segment? Which of the axioms A_1–A_5 are valid?

The congruence relations on the other hand can easily be defined in a geometrically meaningful way. We simply exchange the Euclidean motion group E(2) for the orthogonal group O(3). One needs to pay attention to the fact that for an orthogonal matrix $A \in O(3)$ and $p \in S^2$ the point Ap should lie on S^2 again, i.e. A indeed maps S^2 to itself only.

Exercise 1.20 Show that axioms K_1–K_6 are valid.

There are no parallels since any two great circles intersect. Theorem 1.1.9 therefore does not hold. This is one of the ways to see that not all incidence and ordering axioms can hold.

Because of its importance in navigation, amony other things, spherical geometry has been studied for a very long time. We will investigate it in more detail in sections 4.9 and 4.10.

5- N2 3

Conclusion

$$N_1(p) = N_2(p) \quad \Leftrightarrow \quad \det(D_{u_1}\varphi) > 0$$
$$N_1(p) = -N_2(p) \quad \Leftrightarrow \quad \det(D_{u_1}\varphi) < 0.$$

The following theorem follows immediately.

Theorem 3.4.7 *A regular surface $S \subset \mathbb{R}^3$ is orientable if and only if S can be covered by local parametrisations such that for all parameter transformations φ*

$$\det(D\varphi) > 0.$$

3.5 The second fundamental form

Let $S \subset \mathbb{R}^3$ be an orientable regular surface with smooth unit normal field N. Regarded as a map between surfaces, i.e. $N : S \to S^2$, the map N is also called the ***Gauss map***.

Let $p \in S$. We consider the differential of N at p:

$$d_pN : T_pS \to T_{N(p)}S^2.$$

Now $T_{N(p)}S^2 = N(p)^\perp = T_pS$. Hence d_pN is an endomorphism on T_pS.

Definition 3.5.1 Let $S \subset \mathbb{R}^3$ be a regular surface with orientation given by the unit normal field N. The endomorphism

$$W_p : T_pS \to T_pS,$$

$$W_p(X) = -d_pN(X),$$

is called the ***Weingarten map***.

The negative sign appears for historic reasons. If orientation is reversed, i.e. if $-N$ is substituted for N, then W also changes its sign.

Example 3.5.2 Let $S = S^2$, and let N be the outer unit normal field, $N(p) = p$. Then

$$W_p = -\operatorname{Id} : T_pS^2 \to T_pS^2.$$

Example 3.5.3 Let $S = \{(x,y,0)^\top \mid x,y \in \mathbb{R}\}$ be the x–y plane, $N(x,y,z) = (0,0,1)^\top$. Then N is constant and thus $W_p = 0$ for all $p \in S$.

Example 3.5.4 Let $S = S^1 \times \mathbb{R}$ be the cylinder, $N(x,y,z) = (x,y,0)^\top$.

At a point $p = (x,y,z)^\top \in S$ the tangent plane T_pS is spanned by the basis vectors $(-y,x,0)^\top$ and $(0,0,1)^\top$. We calculate

$$W_p\begin{pmatrix}0\\0\\1\end{pmatrix} = -d_pN\begin{pmatrix}0\\0\\1\end{pmatrix} = -\frac{d}{dt}N\left.\begin{pmatrix}x\\y\\z+t\end{pmatrix}\right|_{t=0}$$
$$= -\frac{d}{dt}\left.\begin{pmatrix}x\\y\\0\end{pmatrix}\right|_{t=0} = \begin{pmatrix}0\\0\\0\end{pmatrix}.$$

To find the image of $(-y, x, 0)$ under W_p, we choose $t_0 \in \mathbb{R}$, such that $(\cos(t_0), \sin(t_0)) = (x, y)$. Then for $c(t) := (\cos(t + t_0), \sin(t + t_0), z)^\top$ we have that $c(0) = (x, y, z)^\top = p$ and $\dot{c}(0) = (-\sin(t_0), \cos(t_0), 0)^\top = (-y, x, 0)^\top$. It follows that

$$W_p\begin{pmatrix}-y\\x\\0\end{pmatrix} = -d_pN\begin{pmatrix}-y\\x\\0\end{pmatrix} = -\frac{d}{dt}N\left.\begin{pmatrix}\cos(t+t_0)\\\sin(t+t_0)\\z\end{pmatrix}\right|_{t=0}$$
$$= -\frac{d}{dt}\left.\begin{pmatrix}\cos(t+t_0)\\\sin(t+t_0)\\0\end{pmatrix}\right|_{t=0} = \begin{pmatrix}\sin(t_0)\\-\cos(t_0)\\0\end{pmatrix} = -\begin{pmatrix}-y\\x\\0\end{pmatrix}.$$

With respect to the basis vectors $(-y, x, 0)^\top$ and $(0, 0, 1)^\top$, the map W_p therefore has the matrix representation

$$\begin{pmatrix}-1 & 0\\ 0 & 0\end{pmatrix}.$$

Proposition 3.5.5 *Let $S \subset \mathbb{R}^3$ be an orientable regular surface with Weingarten map $W_p : T_pS \to T_pS$, $p \in S$. Then W_p is self-adjoint with respect to the first fundamental form.*

Proof Let N be the unit normal field of S that induces the Weingarten map, $W_p = -d_pN$. We choose a local parametrisation (U, F, V) at p and set $u := F^{-1}(p)$.

Let

$$X_1 := D_uF(e_1) = \frac{\partial F}{\partial u^1}(u)$$

and

$$X_2 := D_uF(e_2) = \frac{\partial F}{\partial u^2}(u)$$

be the corresponding basis vectors of T_pS. As N is perpendicular to S everywhere, we have

$$\left\langle \frac{\partial F}{\partial u^i}(u+te_j),\ N(F(u+te_j)) \right\rangle \equiv 0.$$

Differentiating this equation with respect to t gives

$$\begin{aligned} 0 &= \frac{d}{dt} \left\langle \frac{\partial F}{\partial u^i}(u+te_j), N(F(u+te_j)) \right\rangle \bigg|_{t=0} \\ &= \left\langle \frac{d}{dt} \frac{\partial F}{\partial u^i}(u+te_j) \bigg|_{t=0}, N(p) \right\rangle + \left\langle \frac{\partial F}{\partial u^i}(u), d_pN \circ D_uF(e_j) \right\rangle \\ &= \left\langle \frac{\partial^2 F}{\partial u^j \partial u^i}(u), N(p) \right\rangle + \langle X_i, -W_p(X_j) \rangle . \end{aligned}$$

Thus

$$I_p(X_i, W_p(X_j)) = \langle X_i, W_p(X_j) \rangle = \left\langle \frac{\partial^2 F}{\partial u^j \partial u^i}(u), N(p) \right\rangle. \tag{3.3}$$

By the theorem of Schwarz [18, p. 372, theorem 1.1] the two partial derivatives of F can be exchanged and we obtain

$$\begin{aligned} I_p(X_i, W_p(X_j)) &= \left\langle \frac{\partial^2 F}{\partial u^j \partial u^i}(u), N(p) \right\rangle \\ &= \left\langle \frac{\partial^2 F}{\partial u^i \partial u^j}(u), N(p) \right\rangle \\ &= I_p(X_j, W_p(X_i)). \end{aligned}$$

We now know for our basis vectors X_1 and X_2 of T_pS that

$$I_p(X_i, W_p(X_j)) = I_p(X_j, W_p(X_i)) = I_p(W_p(X_i), X_j).$$

Since any two vectors $X, Y \in T_pS$ can be written as a linear combination of X_1 and X_2, it immediately follows from the bilinearity of I and the linearity of W_p that

$$I_p(X, W_p(Y)) = I_p(W_p(X), Y),$$

i.e. W_p is self-adjoint with respect to I. □

Let us recall from linear algebra that if V is a finite-dimensional real vector space with Euclidean scalar product $\langle \cdot, \cdot \rangle$, then the self-adjoint endomorphisms

W on V are uniquely associated with the symmetric bilinear forms β on V. The relation between W and β is

$$\beta(X,Y) = \langle W(X), Y\rangle, \qquad X, Y \in V.$$

Definition 3.5.6 The bilinear form that corresponds to the Weingarten map W_p is called the ***second fundamental form*** (of the surface S at the point p):

$$II_p(X,Y) = I_p(W_p(X), Y), \qquad X, Y \in T_pS.$$

For simplicity the root point vector p is often omitted in the notation, and we write II instead of II_p, and W instead of W_p.

Expression in local coordinates Let $S \subset \mathbb{R}^3$ be a regular surface, $p \in S$. Let (U, F, V) be a local parametrisation of S at p. We set $u := F^{-1}(p)$. We have already learnt how to express the first fundamental form locally. For the basis $D_uF(e_1) = (\partial F/\partial u^1)(u)$ and $D_uF(e_2) = (\partial F/\partial u^2)(u)$ the first fundamental form is given by the symmetric matrix $(g_{ij}(u))_{i,j=1,2}$, where

$$\begin{aligned} g_{ij}(u) &= \left\langle \frac{\partial F}{\partial u^i}(u), \frac{\partial F}{\partial u^j}(u)\right\rangle \\ &= I_p\left(D_uF(e_i), D_uF(e_j)\right). \end{aligned}$$

We now define

$$\begin{aligned} h_{ij}(u) &:= II_p(D_uF(e_i), D_uF(e_j)) \\ &= I_p\left(W_p(D_uF(e_i)), D_uF(e_j)\right) \\ &\overset{(3.3)}{=} \left\langle \frac{\partial^2 F}{\partial u^j \partial u^i}(u), N(p)\right\rangle, \; i,j = 1,2. \end{aligned} \tag{3.4}$$

Then $(h_{ij}(u))_{i,j=1,2}$ is the symmetric matrix which gives the second fundamental form w.r.t. the basis given above. The entries of the matrix representing the Weingarten map are denoted as w_i^j, i.e. we define

$$W_p(D_uF(e_i)) =: \sum_{j=1}^{2} w_i^j(u) D_uF(e_j).$$

As the Weingarten map is closely related to the second fundamental form, we expect that the matrices $(h_{ij}(u))_{i,j}$ and $\left(w_i^j(u)\right)_{i,j}$ can be determined from each other. This works as follows:

$$\begin{aligned}
h_{ij}(u) &= II(D_uF(e_i), D_uF(e_j)) \\
&= I(W(D_uF(e_i)), D_uF(e_j)) \\
&= I\Big(\sum_{k=1}^{2} w_i^k(u) D_uF(e_k), D_uF(e_j)\Big) \\
&= \sum_{k=1}^{2} w_i^k(u) I\left(D_uF(e_k), D_uF(e_j)\right) \\
&= \sum_{k=1}^{2} w_i^k(u) g_{kj}(u).
\end{aligned}$$

The matrix $(h_{ij}(u))_{i,j}$ therefore results from the matrix multiplication of the matrices $\left(w_i^k(u)\right)_{i,k}$ and $(g_{kj}(u))_{k,j}$. As the matrix $(g_{kj}(u))_{k,j}$ is positive definite, and thus in particular is invertible, the equation can be solved for $\left(w_i^k(u)\right)_{i,k}$. For this purpose let $(g^{ij}(u))_{i,j}$ be the inverse matrix of $(g_{ij}(u))_{i,j}$, i.e.

$$\left(g^{ij}(u)\right)_{ij} = \frac{1}{g_{11}(u)g_{22}(u) - g_{12}(u)^2} \begin{pmatrix} g_{22}(u) & -g_{12}(u) \\ -g_{21}(u) & g_{11}(u) \end{pmatrix}.$$

It then follows that

$$\sum_{k=1}^{2} h_{ik}(u) g^{kj}(u) = w_i^j(u). \tag{3.5}$$

3.6 Curvature

We now come to a central notion of surface theory and of differential geometry: ***curvature***. We will meet several concepts of curvature, and we begin with normal curvature.

For this purpose let $S \subset \mathbb{R}^3$ be an orientable regular surface with smooth unit normal field N, $p \in S$. Let $c : (-\varepsilon, \varepsilon) \to S$ be a curve parametrised by arclength with $c(0) = p$. Regarded as a space curve in $\mathbb{R}^3$, the curve c has at point 0 curvature $\kappa(0)$, which in the case $\kappa(0) \neq 0$ is given by

$$\ddot{c}(0) = \kappa(0) \cdot n(0),$$

where n is the normal vector of c. We now want to split this curvature into a part which results from the fact that c curves *within* S, and a part which reflects the curvature of S in $\mathbb{R}^3$. For this purpose we decompose $n(0)$ into a part that is tangential to S and one that is perpendicular to S:

$$n(0) = n(0)^{\text{tang}} + n(0)^{\text{perp}},$$

where $n(0)^{\text{perp}} = \langle n(0), N(p)\rangle\, N(p)$. We therefore have

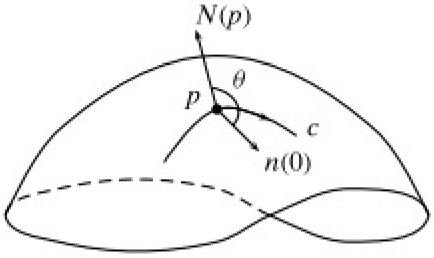
$$\ddot{c}(0) = \kappa(0) \cdot n(0) = \kappa(0) \cdot n(0)^{\text{tang}} + \kappa(0) \cdot \langle n(0), N(p)\rangle\, N(p).$$

The tangential part, which gives the extent to which c curves within S, leads to the ***geodesic curvature*** of c in S, to which we will come back in section 4.5. For now we are interested in the curvature of S in $\mathbb{R}^3$, and for this reason make the definition

$$\kappa_{\text{nor}} := \langle \ddot{c}(0), N(p)\rangle = \begin{cases} \kappa(0) \cdot \langle n(0), N(p)\rangle, & \text{if } \kappa(0) \neq 0, \\ 0, & \text{if } \kappa(0) = 0. \end{cases}$$

We call κ_{nor} the ***normal curvature*** of S at the point p in direction $\dot{c}(0)$. If, in the case of $\kappa(0) \neq 0$, θ denotes the angle between $N(p)$ and $n(0)$, then we therefore have

$$\kappa_{\text{nor}} = \kappa(0) \cdot \cos(\theta).$$



In particular, we always have

$$|\kappa_{\text{nor}}| \leq \kappa(0).$$

The following theorem tells us how to find the normal curvature from the second fundamental form.

Theorem 3.6.1 (Meusnier's theorem) *Let $S \subset \mathbb{R}^3$ be an orientable regular surface with unit normal field N and second fundamental form II. Let $p \in S$. Let $c : (-\varepsilon, \varepsilon) \to S$ be a curve parametrised by arc-length with $c(0) = p$. Then we have for the normal curvature κ_{nor} of c:*

$$\kappa_{\text{nor}} = II(\dot{c}(0), \dot{c}(0)).$$

In particular, all curves parametrised by arc-length in S through p with the same tangent vector have the same normal curvature.

This also justifies that we refer to κ_{nor} as the normal curvature of S at the point p in direction $\dot{c}(0)$, since κ_{nor} depends, apart from on S and p, only on $\dot{c}(0)$, but not on the particular choice of the curve c.

Proof As c lies on S, we have

$$\langle N(c(t)), \dot{c}(t)\rangle = 0$$

for all $t \in (-\varepsilon, \varepsilon)$. Differentiating this equation gives

$$\begin{aligned} 0 &= \frac{d}{dt}\langle N(c(t)), \dot{c}(t)\rangle\Big|_{t=0} \\ &= \left\langle \frac{d}{dt} N(c(t))\Big|_{t=0}, \dot{c}(0)\right\rangle + \langle N(p), \ddot{c}(0)\rangle \\ &= \langle d_pN(\dot{c}(0)), \dot{c}(0)\rangle + \kappa_{\text{nor}} \\ &= \langle -W_p(\dot{c}(0)), \dot{c}(0)\rangle + \kappa_{\text{nor}} \\ &= -II(\dot{c}(0), \dot{c}(0)) + \kappa_{\text{nor}}. \end{aligned}$$

□

Remark A change of orientation of the curve c does not change the value of the normal curvature κ_{nor}, since

$$II(-\dot{c}(0), -\dot{c}(0)) = II(\dot{c}(0), \dot{c}(0)).$$

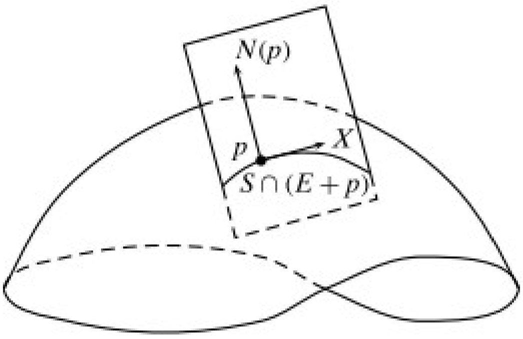
However, if the orientation of the surface S is reversed with $N(p)$ being replaced by $-N(p)$, curvature κ_{nor} changes sign:

$$\langle \ddot{c}(0), -N(p)\rangle = -\langle \ddot{c}(0), N(p)\rangle.$$

Let $S \subset \mathbb{R}^3$ be an orientable regular surface with unit normal field N, let $p \in S$. Let $X \in T_pS$ be a tangent vector of length 1.

Exercise 3.9 Let E be the plane spanned by $N(p)$ and X. Use the implicit mapping theorem to show that for a neighbourhood V of p in $\mathbb{R}^3$ the set

$S \cap (E + p) \cap V$ can be parametrised by a regular curve. Here $E + p$ denotes the plane E translated to the point p.

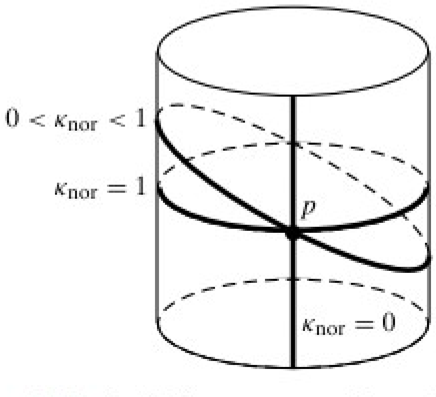


According to theorem 3.6.1 the normal curvature $II(X, X)$ can be found from the unit speed curve c which describes $S \cap (E + p) \cap V$. If we consider c as a plane curve in the plane $E + p \cong \mathbb{R}^2$, then the normal vector of the curve $n(0) = \pm N(p)$ and hence the normal curvature is

$$II(X, X) = \pm\kappa(0),$$

where κ is the curvature of c considered as a plane curve. This explains the term *normal* curvature. The normal curvature is the curvature of the plane curve $S \cap (E + p) \cap V$ in the plane E spanned by X and the normal vector.

Example 3.6.2 Let $S = S^1 \times \mathbb{R}$ be the cylinder. Let $p \in S$. The intersection of S with the normal plane at the point p is a circle, an ellipse or a straight line. The normal curvature therefore varies between 1 and 0, depending on the direction.



$0 < \kappa_{\text{nor}} < 1$
$\kappa_{\text{nor}} = 1$
p
$\kappa_{\text{nor}} = 0$

By proposition 3.5.5 the Weingarten map $W_p : T_pS \to T_pS$ is always self-adjoint. We can therefore find an orthonormal basis X_1, X_2 of T_pS, which

5- 6/2 /<3 *) %)
5- 672 N 3) ; D -))4 E) *) %)

By (3.4) the second fundamental form is

$$\begin{aligned}
h_{11}(t,\varphi) &= \left\langle \frac{\partial^2 F}{\partial t^2}(t,\varphi), N(t,\varphi) \right\rangle \\
&= \left(\kappa(t)(1 - r\cos(\varphi)\kappa(t)) - r\sin(\varphi)\dot{\tau}(t) - r\cos(\varphi)\tau(t)^2\right)(-\cos(\varphi)) \\
&\quad + (-\sin(\varphi)\tau(t)^2 + \cos(\varphi)\dot{\tau}(t))(-\sin(\varphi)) \\
&= r\tau(t)^2 - \cos(\varphi)\kappa(t) + r\cos(\varphi)^2\kappa(t)^2, \\
h_{12}(t,\varphi) &= r\cos(\varphi)^2\tau(t) + r\sin(\varphi)^2\tau(t) \\
&= r\tau(t), \\
h_{22}(t,\varphi) &= r.
\end{aligned}$$

From (3.5) it follows that the matrix of the Weingarten map is

$$\begin{aligned}
\left(w_i^j(t,\varphi)\right)_{ij} &= (h_{ik}(t,\varphi))(g^{kj}(t,\varphi)) \\
&= \begin{pmatrix} r\tau(t)^2 - \cos(\varphi)\kappa(t) + r\cos(\varphi)^2\kappa(t)^2 & r\tau(t) \\ r\tau(t) & r \end{pmatrix} \cdot \\
&\quad \cdot \begin{pmatrix} \dfrac{1}{(1 - r\cos(\varphi)\kappa(t))^2} & -\dfrac{\tau(t)}{(1 - r\cos(\varphi)\kappa(t))^2} \\ -\dfrac{\tau(t)}{(1 - r\cos(\varphi)\kappa(t))^2} & \dfrac{1}{r^2} + \dfrac{\tau(t)^2}{(1 - r\cos(\varphi)\kappa(t))^2} \end{pmatrix} \\
&= \begin{pmatrix} -\dfrac{\kappa(t)\cos(\varphi)}{1 - r\cos(\varphi)\kappa(t)} & * \\ 0 & \dfrac{1}{r} \end{pmatrix}.
\end{aligned}$$

As this matrix is triangular, we can read off the eigenvalues and obtain the principal curvatures:

$$\begin{aligned}
\kappa_1 &= \frac{-\kappa(t)\cos(\varphi)}{1 - r\cos(\varphi)\kappa(t)}, \\
\kappa_2 &= \frac{1}{r}.
\end{aligned}$$

It follows that the Gauss curvature is

$$K = -\frac{1}{r}\frac{\kappa(t)\cos(\varphi)}{1 - r\cos(\varphi)\kappa(t)},$$

and the mean curvature is

$$H = \frac{1 - 2r\cos(\varphi)\kappa(t)}{2r(1 - r\cos(\varphi)\kappa(t))}.$$

Example 3.8.18 We consider the ***torus***, which is defined as the tubular surface around a circular line

$$c(t) = (\cos(t), \sin(t), 0)^\top$$

with thickness $2r < 2$ (plate 7). We then have

$$\kappa(t) \equiv 1, \quad \tau(t) \equiv 0$$

and thus

$$K(t,\varphi) = -\frac{1}{r}\frac{\cos(\varphi)}{1 - r\cos(\varphi)}, \quad H(t,\varphi) = \frac{\cos(\varphi) - r/2}{1 - r\cos(\varphi)}.$$

Exercise 3.32 Let c be a closed space curve parametrised by arc-length. Show that for every tubular surface S around c we have

$$\int_S K\,dA = 0.$$

We will understand this fact better against the background of the Gauss–Bonnet theorem.

Exercise 3.33 Let $c : I \to \mathbb{R}^3$ be a closed space curve. Using the results of this section and exercise 3.16 give a new simple proof of the total curvature estimate in Fenchel's theorem 2.3.19:

$$\kappa(c) \geq 2\pi.$$

The most important geometric quantities of a regular surface are summarised in tables 4.1 and 4.2.

4.4 Riemannian metrics

Since we will as of now just look at quantities that depend on the inner geometry only, we will at this point generalise the concept of the first fundamental form. What actually is the first fundamental form? It assigns a Euclidean scalar product to each tangent plane. That this scalar product is the restriction of the standard scalar product on $\mathbb{R}^3$ is of no importance for quantities that depend on the inner geometry only. We therefore make the following definition.

Definition 4.4.1 Let $S \subset \mathbb{R}^3$ be a regular surface. A ***Riemannian metric*** g on S assigns a Euclidean scalar product g_p on the tangent plane T_pS to each point $p \in S$, such that for every local parametrisation (U, F, V) of S the functions

$$g_{ij} : U \to \mathbb{R},$$
$$g_{ij}(u) := g_{F(u)}\left(\frac{\partial F}{\partial u^i}(u), \frac{\partial F}{\partial u^j}(u)\right)$$

are smooth.

The first fundamental form is, of course, an example of a Riemannian metric. But there are important examples of Riemannian metrics that are not the first fundamental form, as we will see later. One of them is the hyperbolic plane. The condition that the functions g_{ij} must be smooth ensures the scalar product g_p does not "wildly" depend on p, but is differentiable w.r.t. p. In the case of the first fundamental form this holds automatically.

All quantities that depend on the inner geometry only, such as the surface element, the covariant derivative, the Gauss curvature and the Riemann curvature tensor, are also defined for regular surfaces with a Riemannian metric that is not the first fundamental form.

We therefore *define*, for example, the Christoffel symbols via the formula from lemma 4.2.14 as

$$\Gamma_{ij}^k := \frac{1}{2}\sum_{m=1}^{2}\left(\frac{\partial g_{jm}}{\partial u^i} + \frac{\partial g_{im}}{\partial u^j} - \frac{\partial g_{ij}}{\partial u^m}\right) g^{mk} \tag{4.7}$$

and then the covariant derivative for vector fields

$$v = \sum_i v^i \frac{\partial F}{\partial u^i}, w = \sum_j w^j \frac{\partial F}{\partial u^j}$$

via

$$\nabla_w v(F(u)) := \sum_k \left(d_u v^k \begin{pmatrix} w^1(u) \\ w^2(u) \end{pmatrix} + \sum_{ij} \Gamma_{ij}^k(u) v^i(u) w^j(u) \right) \frac{\partial F}{\partial u^k}(u).$$

Of course, it needs to be checked that this definition does not depend on the local parametrisation chosen; this is left as an exercise for the reader. In the case of the first fundamental form this formula holds automatically. We can analogously translate the other quantities that depend on the inner geometry, such as the Riemann curvature tensor and the Gauss curvature. We see that it was good to have required the smoothness of the g_{ij}. For the definition of the covariant derivative we need the first derivatives of the g_{ij}, for the curvature we also need the second derivatives.

Exercise 4.13 Show that lemma 4.2.12 and lemma 4.2.17 also hold for general Riemannian metrics.

Exercise 4.14 Show that for any two smooth vector fields v and w on a regular surface equipped with a Riemannian metric one has

$$\nabla_v w - \nabla_w v = [v, w].$$

5- TN2 63

$x \in \mathbb{R}^2$. The geodesic equation (4.11) then becomes

$$\sum_{ij} \Gamma_{ij}^k(tx)x^i x^j = 0, \quad k = 1, 2.$$

For $t = 0$ in particular we therefore have

$$\sum_{ij} \Gamma_{ij}^k(0,0)x^i x^j = 0, \quad k = 1, 2,$$

for all x. As $\Gamma_{ij}^k(0,0)$ is symmetric in i and j for fixed k, we can polarise and obtain

$$\Gamma_{ij}^k(0,0) = 0$$

for all i, j, k. From (4.3)

$$\frac{\partial g_{jm}}{\partial u^i} = \sum_k \left(\Gamma_{ij}^k g_{km} + \Gamma_{im}^k g_{kj} \right),$$

it follows that

$$\frac{\partial g_{ij}}{\partial u^k}(0,0) = 0$$

for all i, j, k. ☐

Example 4.6.8 As above, let S be an arbitrary regular surface with a Riemannian metric, let $p \in S$ and let X_1, X_2 be an orthonormal basis of T_pS. This time we take polar coordinates for T_pS, $F_1(r, \varphi) = r \cdot (\cos(\varphi)X_1 + \sin(\varphi)X_2)$. The corresponding local parametrisation of S,

$$F(r, \varphi) = \exp_p \left(r \cdot (\cos(\varphi)X_1 + \sin(\varphi)X_2) \right),$$

is the parametrisation in ***geodesic polar coordinates*** (at the point p).

Theorem 4.6.9 (Gauss's lemma) *Let S be a regular surface with Riemannian metric g. Let $p \in S$ and let F be a local parametrisation in geodesic coordinates (r, φ).*

Then the Riemannian metric has the following form with respect to the local parametrisation:

$$(g_{ij}(r, \varphi))_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & f(r, \varphi)^2 \end{pmatrix},$$

with a positive function f that satisfies

$$\lim_{r \to 0} f(r, \varphi) = 0, \qquad \lim_{r \to 0} \frac{\partial f}{\partial r}(r, \varphi) = 1.$$

Proof Let X_1, X_2 be the orthonormal basis of T_pS that we have used for the definition of the geodesic polar coordinates, $F(r,\varphi) = \exp_p(\tilde{F}(r,\varphi))$, where $\tilde{F}(r,\varphi) = r\cdot(\cos(\varphi)X_1 + \sin(\varphi)X_2)$. The curve $c(r) = F(r,\varphi_0)$ is for fixed $\varphi = \varphi_0$ by the definition of the exponential map the geodesic with $\dot{c}(0) = \cos(\varphi_0)X_1 + \sin(\varphi_0)X_2$. Geodesics are parametrised proportional to arc-length and $\dot{c}(0)$ is a unit vector, hence

$$g_{11}(r,\varphi_0) = g(\dot{c}(r),\dot{c}(r)) = 1.$$

Further

$$\begin{aligned}
\frac{\partial g_{12}}{\partial r}(r,\varphi_0) &= \frac{\partial}{\partial r} g\left(\frac{\partial F}{\partial r},\frac{\partial F}{\partial \varphi}\right)\Big|_{(r,\varphi_0)} \\
&= g\left(\frac{\nabla}{\partial r}\frac{\partial F}{\partial r}(r,\varphi_0),\frac{\partial F}{\partial \varphi}(r,\varphi_0)\right) + g\left(\frac{\partial F}{\partial r}(r,\varphi_0),\frac{\nabla}{\partial r}\frac{\partial F}{\partial \varphi}(r,\varphi_0)\right) \\
&= g\left(\frac{\nabla}{dr}\dot{c}(r),\frac{\partial F}{\partial \varphi}(r,\varphi_0)\right) + g\left(\frac{\partial F}{\partial r}(r,\varphi_0),\frac{\nabla}{\partial r}\frac{\partial F}{\partial \varphi}(r,\varphi_0)\right) \\
&= 0 + g\left(\frac{\partial F}{\partial r}(r,\varphi_0),\frac{\nabla}{\partial \varphi}\frac{\partial F}{\partial r}(r,\varphi_0)\right) \\
&= \frac{1}{2}\,\frac{\partial}{\partial \varphi}\underbrace{g\left(\frac{\partial F}{\partial r},\frac{\partial F}{\partial r}\right)}_{=1}\Bigg|_{(r,\varphi_0)} \\
&= 0. \qquad (4.13)
\end{aligned}$$

Hence the function g_{12} is constant in r for fixed $\varphi = \varphi_0$. As an abbreviation we set $Y_1 := \cos(\varphi_0)X_1 + \sin(\varphi_0)X_2$ and $Y_2 := -\sin(\varphi_0)X_1 + \cos(\varphi_0)X_2$. This is the orthonormal basis of T_pS that results from X_1, X_2 in a rotation through the angle φ_0. We have

$$\frac{\partial \tilde{F}}{\partial r}(r,\varphi_0) = Y_1, \qquad \frac{\partial \tilde{F}}{\partial \varphi}(r,\varphi_0) = r\cdot Y_2.$$

We calculate

$$\begin{aligned}
\lim_{r\to 0} g_{12}(r,\varphi_0) &= \lim_{r\to 0} g\left(\frac{\partial F}{\partial r}(r,\varphi_0),\frac{\partial F}{\partial \varphi}(r,\varphi_0)\right) \\
&= \lim_{r\to 0} g\left(d_{\tilde{F}(r,\varphi_0)}\exp_p\left(\frac{\partial \tilde{F}}{\partial r}(r,\varphi_0)\right), d_{\tilde{F}(r,\varphi_0)}\exp_p\left(\frac{\partial \tilde{F}}{\partial \varphi}(r,\varphi_0)\right)\right)
\end{aligned}$$

$$\begin{aligned}
&= \lim_{r\to 0} g\left(d_{\tilde{F}(r,\varphi_0)} \exp_p(Y_1), d_{\tilde{F}(r,\varphi_0)} \exp_p(r \cdot Y_2)\right)\\
&= g\left(d_0 \exp_p(Y_1), d_0 \exp_p(0)\right)\\
&= 0. \qquad (4.14)
\end{aligned}$$

From (4.13) and (4.14) it follows that

$$g_{12} = g_{21} = 0.$$

Hence

$$(g_{ij})_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & g_{22} \end{pmatrix}.$$

As the Riemannian metric is positive definite, we have $g_{22} > 0$ and we can write $g_{22} = f^2$. In a way similar to that used in (4.14) we calculate

$$\begin{aligned}
\lim_{r\to 0} g_{22}(r,\varphi_0) &= \lim_{r\to 0} g\left(d_{\tilde{F}(r,\varphi_0)} \exp_p\left(\frac{\partial \tilde{F}}{\partial \varphi}(r,\varphi_0)\right), d_{\tilde{F}(r,\varphi_0)} \exp_p\left(\frac{\partial \tilde{F}}{\partial \varphi}(r,\varphi_0)\right)\right)\\
&= \lim_{r\to 0} g\left(d_{\tilde{F}(r,\varphi_0)} \exp_p(r \cdot Y_2), d_{\tilde{F}(r,\varphi_0)} \exp_p(r \cdot Y_2)\right)\\
&= g\left(d_0 \exp_p(0), d_0 \exp_p(0)\right)\\
&= 0.
\end{aligned}$$

This proves that

$$\lim_{r\to 0} f(r,\varphi_0) = 0.$$

Further,

$$\begin{aligned}
\lim_{r\to 0} \frac{\partial f}{\partial r}(r,\varphi_0) &= \lim_{r\to 0} \frac{f(r,\varphi_0)}{r}\\
&= \lim_{r\to 0} \sqrt{\frac{g_{22}(r,\varphi_0)}{r^2}}\\
&= \sqrt{\lim_{r\to 0} \frac{g_{22}(r,\varphi_0)}{r^2}}\\
&= \sqrt{\lim_{r\to 0} g\left(d_{\tilde{F}(r,\varphi_0)} \exp_p(Y_2), d_{\tilde{F}(r,\varphi_0)} \exp_p(Y_2)\right)}\\
&= \sqrt{g\left(d_0 \exp_p(Y_2), d_0 \exp_p(Y_2)\right)}\\
&= \sqrt{g\left(Y_2, Y_2\right)}\\
&= 1. \qquad \square
\end{aligned}$$

Observe that polar coordinates are not defined for $r = 0$. The differential of the parametrisation F does not have full rank. The point p itself cannot be given in terms of geodesic coordinates at the point p. We cannot therefore evaluate the function f at $r = 0$, though we can consider the limit as r tends to 0. However, we can give p in terms of Riemann normal coordinates at p.

Lemma 4.6.10 *Keep the notation from theorem 4.6.9. Then the Gauss curvature satisfies*

$$K(F(r,\varphi)) = -\frac{1}{f(r,\varphi)}\frac{\partial^2 f}{\partial r^2}(r,\varphi).$$

Proof Theorem 4.6.9 tells us that in geodesic coordinates the Riemannian metric has the form

$$(g_{ij}(r,\varphi))_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & f(r,\varphi)^2 \end{pmatrix}.$$

The inverse matrix is then

$$(g^{ij}(r,\varphi))_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & f(r,\varphi)^{-2} \end{pmatrix}.$$

Using the formula

$$\Gamma_{ij}^k = \frac{1}{2}\sum_{m=1}^{2}\left(\frac{\partial g_{jm}}{\partial u^i} + \frac{\partial g_{im}}{\partial u^j} - \frac{\partial g_{ij}}{\partial u^m}\right)g^{mk}$$

from lemma 4.2.14, we easily calculate

$$\begin{aligned}
\Gamma_{11}^1 &= \Gamma_{11}^2 = \Gamma_{12}^1 = \Gamma_{21}^1 = 0,\\
\Gamma_{12}^2 &= \Gamma_{21}^2 = \frac{1}{f}\frac{\partial f}{\partial r},\\
\Gamma_{22}^1 &= -f\cdot\frac{\partial f}{\partial r},\\
\Gamma_{22}^2 &= \frac{1}{f}\frac{\partial f}{\partial \varphi}.
\end{aligned}$$

The vectors $\partial F/\partial r$ and $(1/f)(\partial F/\partial\varphi)$ form an orthonormal basis of the tangent plane. According to the *Theorema Egregium* (theorem 4.3.8) the Gauss curvature is given by

$$\begin{aligned}
K &= g\left(R\left(\frac{\partial F}{\partial r}, \frac{1}{f}\frac{\partial F}{\partial \varphi}\right)\frac{1}{f}\frac{\partial F}{\partial \varphi}, \frac{\partial F}{\partial r}\right) \\
&= \frac{1}{f^2}R^1_{122} \\
&= \frac{1}{f^2}\left(\frac{\partial \Gamma^1_{22}}{\partial r} - \frac{\partial \Gamma^1_{21}}{\partial \varphi} + \Gamma^1_{11}\Gamma^1_{22} - \Gamma^1_{12}\Gamma^1_{21} + \Gamma^1_{21}\Gamma^2_{22} - \Gamma^1_{22}\Gamma^2_{21}\right) \\
&= \frac{1}{f^2}\left(-\left(\frac{\partial f}{\partial r}\right)^2 - f\cdot\frac{\partial^2 f}{\partial r^2} - 0 + 0 - 0 + 0 + f\cdot\frac{\partial f}{\partial r}\cdot\frac{1}{f}\cdot\frac{\partial f}{\partial r}\right) \\
&= -\frac{1}{f}\frac{\partial^2 f}{\partial r^2}.
\end{aligned}$$ □

Remark In geodesic coordinates the function f carries the complete information about the Riemannian metric. We have seen that Gauss curvature can easily be calculated from f. Let us investigate which requirements on f correspond to the condition of constant Gauss curvature $K \equiv \kappa$. The condition

$$\kappa = -\frac{1}{f(r,\varphi)}\frac{\partial^2 f}{\partial r^2}(r,\varphi)$$

is equivalent to

$$\frac{\partial^2 f}{\partial r^2}(r,\varphi) = -\kappa \cdot f(r,\varphi).$$

This is an *ordinary* differential equation in $r \mapsto f(r,\varphi)$ if we keep φ fixed. This, together with the initial conditions $f(0,\varphi) = 0$ and $(\partial f/\partial r)(0,\varphi) = 1$, uniquely determines the solution, which is

$$f(r,\varphi) = \begin{cases} \frac{1}{\sqrt{\kappa}}\sin(\sqrt{\kappa}\cdot r), & \kappa > 0, \\ r, & \kappa = 0, \\ \frac{1}{\sqrt{-\kappa}}\sinh(\sqrt{-\kappa}\cdot r), & \kappa < 0. \end{cases}$$

This shows, in particular, that κ uniquely determines the metric in the coordinate neighbourhood.

Corollary 4.6.11 *If S_1 and S_2 are two regular surfaces with the same constant Gauss curvature κ, then S_1 and S_2 are locally isometric.*

We now see that the inhabitants of the surface from the introduction of this chapter about the inner geometry of surfaces cannot distinguish different surfaces with the same constant Gauss curvature if they can only take measurements in the close neighbourhood of a point. In particular, they cannot distinguish the plane, the cylinder and the cone.

For the proof of the Gauss–Bonnet formula in the last chapter we will need the following formula, which expresses the integral of Gauss curvature in the neighbourhood of a point. For a regular surface S with Riemannian metric g, a point $p \in S$ and $r > 0$ let

$$\bar{D}(p,r) := \{q \in S \mid \exists \text{ geodesic } c : [0,1] \to S \text{ with } c(0) = p, c(1) = q, L[c] \leq r\}.$$

Lemma 4.6.12 *Keep the notation from theorem 4.6.9. Let $r > 0$ be such that $\bar{D}(p,r)$ is (up to a zero set) covered by the geodesic polar coordinate system. Then*

$$\int_{\bar{D}(p,r)} K \, dA = 2\pi - \int_{\varphi_0}^{\varphi_0+2\pi} \frac{\partial f}{\partial r}(r,\varphi)\, d\varphi.$$

Proof By the formula for the Riemannian metric from Gauss's lemma the surface element is given in geodesic polar coordinates by

$$dA = \sqrt{1 \cdot f^2}\, dr\, d\varphi = f\, dr\, d\varphi.$$

For the geodesic coordinate system to cover $\bar{D}(p,r)$ up to a zero set, the domain of the local parametrisation must be of the form $U = (0,R) \times (\varphi_0, \varphi_0 + 2\pi)$ with $R \geq r$. We substitute the formula for Gauss curvature from lemma 4.6.10 and obtain

$$\begin{aligned}\int_{\bar{D}(p,r)} K\, dA &= -\int_{\varphi_0}^{\varphi_0+2\pi} \int_0^r \frac{1}{f(r,\varphi)} \frac{\partial^2 f}{\partial r^2}(r,\varphi) f(r,\varphi)\, dr\, d\varphi \\ &= -\int_{\varphi_0}^{\varphi_0+2\pi} \int_0^r \frac{\partial^2 f}{\partial r^2}(r,\varphi)\, dr\, d\varphi \\ &= -\int_{\varphi_0}^{\varphi_0+2\pi} \left(\frac{\partial f}{\partial r}(r,\varphi) - 1\right) d\varphi.\end{aligned}$$

The last equality holds since $\lim_{r\to 0} (\partial f/\partial r)(r,\varphi) = 1$. ☐

Having looked at Riemann normal coordinates and geodesic polar coordinates, we now introduce coordinates that are particularly tailored to a given curve on the surface.

Lemma 4.6.13 *Let S be a regular surface with Riemannian metric g. Let $c : I \to S$ be a curve parametrised by arc-length, defined on an open interval I. Let $n : I \to \mathbb{R}^3$ be a vector field on S along c that has constant length 1 and $\langle \dot{c}, n \rangle \equiv 0$. Then there is for $t_0 \in I$ an $\varepsilon > 0$, such that*

$$F : (t_0 - \varepsilon, t_0 + \varepsilon) \times (-\varepsilon, \varepsilon) \to S, \quad F(t,s) := \exp_{c(t)}(sn(t)),$$

is a local parametrisation of S. Along c the Riemannian metric w.r.t. this parametrisation has the form

$$\big(g_{ij}(t,0)\big)_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

Proof The partial derivatives of F at the point $(t,0)$ are given by

$$\frac{\partial F}{\partial t}(t,0) = \frac{d}{dt}\exp_{c(t)}(0) = \dot{c}(t)$$

and

$$\frac{\partial F}{\partial s}(t,0) = n(t)$$

and hence form an orthonormal basis of $T_{c(t)}S$. By the inverse function theorem, F is then after a suitable restriction a local parametrisation. Because of the orthonormality the statement about the $g_{ij}(t,0)$ is clear as well. ☐

Definition 4.6.14 The coordinates corresponding to such a parametrisation are called ***Fermi coordinates***.

Fermi coordinates will be useful in the proof of the divergence theorem (theorem 5.1.7).

Exercise 4.25 Show that we have for the Christoffel symbols in Fermi coordinates

$$\Gamma^1_{11}(t,0) = \Gamma^2_{12}(t,0) = \Gamma^2_{21}(t,0) = 0, \quad \Gamma^1_{22}(t,s) = \Gamma^2_{22}(t,s) = 0,$$

$$\Gamma^2_{11}(t,0) = \kappa_g(t), \quad \Gamma^1_{12}(t,0) = \Gamma^1_{21}(t,0) = -\kappa_g(t),$$

where κ_g is the geodesic curvature of c (w.r.t. the orientation of S making $(\dot{c}, n)$ positively oriented).

4.7 Parallel transport

If we have two points p and q in a plane $E \subset \mathbb{R}^3$, then we can identify tangent vectors from T_pE with those from T_qE, since $T_pE = T_qE = E$. If we now replace E by a general regular surface $S \subset \mathbb{R}^3$, then this is no longer straightforward, since in general $T_pS \neq T_qS$. In order still to be able to relate tangent planes at different points even on general surfaces we analyse the concept of "parallel" vectors in the plane a bit more carefully.

We can translate a vector $v_0 \in T_pE$ into the corresponding (the same) vector from T_qE in the following way: we choose a connecting smooth curve $c : [a,b] \to E$, $c(a) = p$, $c(b) = q$, and consider along c the constant vector field $v(t) \equiv v_0$ or, put differently, the vector field along c that satisfies $\dot{v} \equiv 0$. Then $v(b) \in T_qE$ is the vector translated to q. This approach can be used without complications on general regular surfaces by simply replacing the usual derivative of v by the covariant derivative.

Definition 4.7.1 Let S be a regular surface with Riemannian metric g. Let $c : I \to S$ be a smooth curve and $v : I \to \mathbb{R}^3$ be a vector field along c. Then v is ***parallel*** if

$$\frac{\nabla}{dt} v \equiv 0.$$

Remark Hence a smooth curve c is a geodesic if and only if its velocity field $\dot{c}$ is parallel.

We now investigate the property of parallelism w.r.t. a local parametrisation. For this purpose let (U, F, V) be a local parametrisation that contains the trace of the curve c, $c(I) \subset V$. Write $v(t) = \sum_k \xi^k(t)(\partial F/\partial u^k)(u(t))$, where $F \circ u = c$. By (4.2)

$$\frac{\nabla}{dt} v \equiv 0$$

is equivalent to

$$\dot{\xi}^k(t) + \sum_{i,j=1}^{2} \Gamma_{ij}^k(\tilde{c}(t))\xi^i(t)\dot{\tilde{c}}_j(t) \equiv 0 \tag{4.15}$$

for $k = 1, 2$. This is a system of *linear* ordinary differential equations of first order in the coefficients ξ^k. Because of the linearity of the system of equations we are in a situation which is better than the one we were in when we were dealing with the geodesic equations. Now solutions do exist not only locally, but on the whole interval I. Taking this into account, together with the fact that we are dealing with a system of first-order differential equations, so that it suffices to give an initial value (an initial derivative is not needed), we obtain through a reasoning similar to that in the proofs of theorems 4.5.11 and 4.5.12 the following theorem.

Theorem 4.7.2 (Existence and uniqueness of the parallel vector field) *Let S be a regular surface with Riemannian metric g. Let $c : I \to S$ be a smooth curve, $t_0 \in I$, $v_0 \in T_{c(t_0)}S$. Then there exists exactly one parallel vector field v along c with $v(t_0) = v_0$.*

Definition 4.7.3 Let S be a regular surface with Riemannian metric g. Let $c : [t_0, t_1] \to S$ be a smooth curve. The map $P_c : T_{c(t_0)}S \to T_{c(t_1)}S$ that maps v_0 to $v(t_1)$, where v is the unique parallel vector field along c with $v(t_0) = v_0$, is called ***parallel transport along*** c.

Proposition 4.7.4 *Let S be a regular surface with Riemannian metric g. Let* $c : [t_0, t_1] \to S$ *be a smooth curve. Then the following hold:*

(i) *If* $v_0 \in T_{c(t_0)}S$, *then the parallel vector field* v *along* c *with* $v(t_0) = v_0$ *is given by* $v(t) = P_{c|[t_0,t]}(v_0)$.

(ii) *The parallel transport* $P_c : T_{c(t_0)}S \to T_{c(t_1)}S$ *is a linear isometry.*

(iii) *Parallel transport is compatible with the reparametrisation of curve, i.e. if* v *is parallel along* c *and* $\varphi : J \to [t_0, t]$ *is a reparametrisation of* c, *then* $v \circ \varphi$ *is parallel along* $c \circ \varphi$.

Proof Statement (i) follows directly from the uniqueness of parallel transport. We have linearity of parallel transport because of the following: let v_0 and w_0 be from $T_{c(t_0)}S$, and let v and w be the parallel vector fields along c with $v(t_0) = v_0$ and $w(t_0) = w_0$. Let $\alpha, \beta \in \mathbb{R}$. Then the vector field $z(t) := \alpha \cdot v(t) + \beta \cdot w(t)$ is parallel to c, since

$$\frac{\nabla}{dt} z = \alpha \cdot \frac{\nabla}{dt} v + \beta \cdot \frac{\nabla}{dt} w = 0.$$

The field z satisfies the initial condition $z(t_0) = \alpha \cdot v_0 + \beta \cdot w_0$. Hence

$$P_c(\alpha \cdot v_0 + \beta \cdot w_0) = z(t_1) = \alpha \cdot v(t_1) + \beta \cdot w(t_1) = \alpha \cdot P_c(v_0) + \beta \cdot P_c(w_0).$$

This proves the linearity of P_c. For two parallel fields v and w along c we have

$$\begin{aligned} \frac{d}{dt} g(v, w) &= g\left(\frac{\nabla}{dt} v, w\right) + g\left(v, \frac{\nabla}{dt} w\right) \\ &= g(0, w) + g(v, 0) \\ &= 0. \end{aligned}$$

Thus $g_{c(t_0)}(v(t_0), w(t_0)) = g_{c(t_1)}(v(t_1), w(t_1))$, i.e.

$$g_{c(t_0)}(v_0, w_0) = g_{c(t_1)}(P_c(v_0), P_c(w_0)).$$

This means precisely that P_c is a linear *isometry*. Statement (ii) has therefore been proved.

Point (iii) follows from lemma 4.2.12:

$$\frac{\nabla}{dt}(v \circ \varphi) = \dot{\varphi} \cdot \left(\frac{\nabla}{dt} v \circ \varphi\right) = 0. \qquad \square$$

Exercise 4.26 Show that parallel transport is a concept of the inner geometry of the surface. More precisely, if $c : I \to S_1$ is a smooth curve, v a smooth vector field along c and $f : S_1 \to S_2$ a local isometry, then v is parallel along c

if and only if $df \circ v$ is parallel along $f \circ c$. Further conclude that the following diagram commutes for $I = [t_0, t_1]$, $c(t_0) = p$, $c(t_1) = q$:

$$\begin{tikzcd}
T_pS_1 \arrow[r, "P_c"] \arrow[d, "d_pf"] & T_qS_1 \arrow[d, "d_qf"] \\
T_{f(p)}S_2 \arrow[r, "P_{f\circ c}"] & T_{f(q)}S_2
\end{tikzcd}$$

As the covariant and the usual derivative agree on the affine plane $E \subset S$, a vector field is parallel along a curve if and only if it is constant. In particular, the parallel transport $P_c : T_pE \to T_qE$ is independent of the curve c that connects the points p and q when we are dealing with the plane. This is not the case on general regular surfaces.

Example 4.7.5 Let S be the conical surface,

$$S = \left\{ (\xi, \eta, \zeta)^\top \;\middle|\; \xi^2 + \eta^2 = \tfrac{1}{3}\zeta^2, \zeta > 0 \right\}.$$

To investigate parallel vector fields along the curve $c : [0, \pi] \to S$, $c(t) = \frac{1}{2}(\sin(2t), \cos(2t), \sqrt{3})^\top$ in S, we consider the x–y plane $\tilde{S} = \mathbb{R}^2 \times \{0\}$. The map

$$f : \tilde{S} \to S, \qquad f(x, y, 0) = \frac{1}{2\sqrt{x^2 + y^2}} \left(x^2 - y^2, 2xy, \sqrt{3}(x^2 + y^2) \right)^\top$$

is a local isometry, see exercise 4.2. The curve $\tilde{c} : [0, \pi] \to \tilde{S}$, $\tilde{c}(t) = (\cos(t), \sin(t), 0)^\top$, satisfies that $c = f \circ \tilde{c}$. In the plane the parallel vector fields are exactly the constant vector fields. The vector field $\tilde{v}(t) = (1, 0, 0)^\top$, for example, is parallel along $\tilde{c}$. It follows that $v := df \circ \tilde{v}$ is parallel along c in S. Using

$$\frac{\partial f}{\partial x} = \frac{1}{\sqrt{x^2 + y^2}} \begin{pmatrix} x - \frac{1}{2}\dfrac{(x^2 - y^2)\,x}{x^2 + y^2} \\ y - \dfrac{x^2 y}{x^2 + y^2} \\ \dfrac{\sqrt{3}}{2} x \end{pmatrix},$$

we calculate

$$\begin{aligned}
v(t) &= d_{\tilde{c}(t)} f(\tilde{v}(t)) \\
&= d_{\tilde{c}(t)} f \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \\
&= \frac{\partial f}{\partial x}(\tilde{c}(t))
\end{aligned}$$

$$= \begin{pmatrix} \cos(t) - \frac{1}{2}\left(\cos(t)^2 - \sin(t)^2\right)\cos(t) \\ \sin(t) - \cos(t)^2 \sin(t) \\ \frac{\sqrt{3}}{2}\cos(t) \end{pmatrix}$$

$$= \begin{pmatrix} \cos(t)\left(1 - \frac{1}{2}\cos(2t)\right) \\ \sin(t)^3 \\ \frac{\sqrt{3}}{2}\cos(t) \end{pmatrix}.$$

In particular, $v(0) = (1/2, 0, \sqrt{3}/2)^\top$ and $v(\pi) = (-1/2, 0, -\sqrt{3}/2)^\top = -v(0)$. The parallel transport changes the tangent vector $v_0 = (1/2, 0, \sqrt{3}/2)^\top$ into its negative in one revolution around c. More generally, v_0 is mapped to itself for an even number k of revolutions, i.e. c, parametrised on $[0, k \cdot \pi]$, is mapped to itself by parallel translation, while it is mapped to $-v_0$ for uneven k.

Exercise 4.27 Illustrate this by drawing a constant vector field along half of a circular line on a sheet of paper, and then making a cone out of the half of the disc.

This example shows that parallel transport generally depends on the connecting curve on regular surfaces.

Exercise 4.28 Let S be a regular surface with Riemannian metric g. Let $c : I \to S$ be a constant curve, $c \equiv p$. A vector field along c is therefore a map $v : I \to T_pS$. Show that v is parallel if and only if v is constant.

4.8 Jacobi fields

We discussed the geometric meaning of Gauss curvature in section 3.6. Theorem 3.6.15 told us how the surface behaves near a point relative to the tangent plane at that point, in terms of the of the sign of the Gauss curvature at that point. But those investigations are only valid for the first fundamental form. In the case of a general Riemannian metric we want to understand what Gauss curvature tells us about the inner geometry of a surface. Jacobi fields are an important tool for this; they, as we will see below, contain information about the behaviour of neighbouring geodesics.

Definition 4.8.1 Let S be a regular surface with Riemannian metric g. Let c be a geodesic on S. A smooth vector field J on S along c is called a ***Jacobi field*** if

$$\frac{\nabla}{dt}\frac{\nabla}{dt}J = -R(J, \dot{c})\dot{c}.$$

This Jacobi equation is a linear ordinary differential equation of second order in J. We can therefore take arbitrary initial values $J(t_0)$ and $(\nabla/dt)J(t_0)$ in

5- 2 T3 @;) 4 6 T 6 E *) %)))) 8 L x y 8
6 N3) 9 % ;4 +

We see that for the interesting Jacobi fields the Jacobi equation is equivalent to the following ordinary differential equation:

$$\ddot{\chi} = -\chi \cdot (K \circ c_0), \tag{4.16}$$

in which the Gauss curvature K plays a significant role. The solution to this differential equation cannot generally be found explicitly very easily. The interesting Jacobi fields give us actual information about the surface that tells us approximately how much neighbouring geodesics (from our geodesic variation) diverge from each other. Let us illustrate this with a simple but important example.

Example 4.8.4 If the Gauss curvature of a surface is constant, $K \equiv \kappa$, then (4.16) can be solved explicitly. Setting

$$\mathfrak{s}_\kappa(t) := \begin{cases} \sin(\sqrt{\kappa}t)/\sqrt{\kappa}, & \kappa > 0, \\ t, & \kappa = 0, \\ \sinh(\sqrt{|\kappa|}t)/\sqrt{|\kappa|}, & \kappa < 0, \end{cases} \qquad \mathfrak{c}_\kappa(t) := \begin{cases} \cos(\sqrt{\kappa}t), & \kappa > 0, \\ 1, & \kappa = 0, \\ \cosh(\sqrt{|\kappa|}t), & \kappa < 0, \end{cases}$$

we have

$$\mathfrak{c}_\kappa(t)^2 + \kappa\mathfrak{s}_\kappa(t)^2 = 1, \tag{4.17}$$

$$\dot{\mathfrak{s}}_\kappa = \mathfrak{c}_\kappa, \tag{4.18}$$

$$\dot{\mathfrak{c}}_\kappa = -\kappa\mathfrak{s}_\kappa. \tag{4.19}$$

In particular, the functions $\mathfrak{s}_\kappa$ and $\mathfrak{c}_\kappa$ solve the differential equation

$$\ddot{\chi} = -\kappa \cdot \chi$$

and are linearly independent. Hence every solution of this differential equation can be written as a linear combination of $\mathfrak{s}_\kappa$ and $\mathfrak{c}_\kappa$. The interesting Jacobi fields are thus of the form

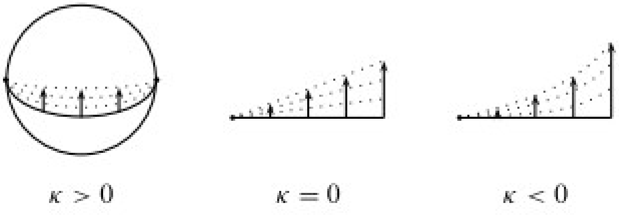
$$J(t) = (\alpha\mathfrak{s}_\kappa(t) + \beta\mathfrak{c}_\kappa(t))n(t).$$

They behave very differently depending on the sign of κ. If $\kappa > 0$, then the length of J is periodic with period $2\pi/\kappa$. In particular, J is 0 again and again. For geodesics that diverge at a point this means that they will approach each other again after some time.

If $\kappa = 0$, then the length increases linearly. This is the familiar situation that we know from straight lines in the Euclidean plane.

6 73

In the case $\kappa < 0$ the length increases even more quickly, in fact exponentially. Summarising we can say that the more negative the curvature, the more the geodesics diverge.



Exercise 4.29 Show that on the surface of revolution with parametrisation $F(t, \varphi) = (r(t)\cos(\varphi), r(t)\sin(\varphi), t)^\top$ the vector field $\partial F/\partial\varphi$ is a Jacobi field along the lines of longitude.

4.9 Spherical and hyperbolic geometry

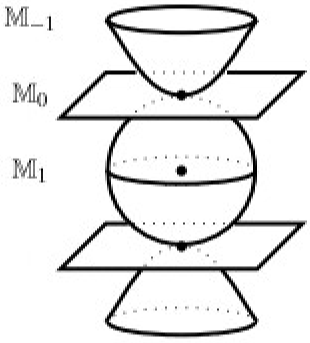
We now want to investigate spherical geometry in more detail, in particular with regard to trigonometric rules analogous to those of Euclidean geometry, which we treated in the first chapter. At the same time we introduce a surface which is in a way the negatively curved analogue of the sphere, the hyperbolic plane. We can investigate its trigonometry simultaneously. The hyperbolic plane has great historic importance, since it satisfies all axioms of Euclidean geometry except for the parallel axiom. It also shows that the efforts to derive the parallel axiom from the other axioms, which had been going on for thousands of years, were inevitably in vain.

Let us construct the hyperbolic plane. For $\kappa \in \mathbb{R}$ we set

$$\widehat{\mathbb{M}}_\kappa := \left\{ (x, y, z)^\top \in \mathbb{R}^3 \,\middle|\, \kappa(x^2 + y^2) + z^2 = 1 \right\}.$$

In the case $\kappa = 1$ this is simply the sphere $\widehat{\mathbb{M}}_1 = S^2$. In the case $\kappa = 0$, on the other hand, we obtain the union of two parallel planes through the points $(0, 0, 1)$ and $(0, 0, -1)$. We are now mostly interested in the case $\kappa = -1$. The surface $\widehat{\mathbb{M}}_{-1}$ is the ***two-sheeted hyperboloid***, consisting of two sheets that are graphs of the functions $z = \pm\sqrt{1 + x^2 + y^2}$. Being graphs, they are, in particular, regular surfaces. Since we do not want to work with several sheets, we additionally define

$$\mathbb{M}_\kappa := \begin{cases} \widehat{\mathbb{M}}_\kappa, & \kappa > 0, \\ \{(x, y, z)^\top \in \widehat{\mathbb{M}}_\kappa \mid z > 0\}, & \kappa \leq 0. \end{cases}$$



So we take only the upper plane or sheet. We already know that $\mathbb{M}_1$ has constant Gauss curvature $K \equiv 1$, while the plane has $K \equiv 0$, in each case with the first fundamental form as Riemannian metric. If we now take the first fundamental form on $\mathbb{M}_{-1}$, then it does not have curvature -1, which we would have liked.

Exercise 4.30 Show that $\mathbb{M}_{-1}$ with the first fundamental form as Riemannian metric has positive Gauss curvature.

Let us therefore take another Riemannian metric on $\mathbb{M}_{-1}$. Indeed, this example is so important that we have already introduced general Riemannian metrics because of this. For the construction of the Riemannian metric we define the following symmetric bilinear form on $\mathbb{R}^3$:

$$\left\langle \begin{pmatrix} x \\ y \\ z \end{pmatrix}, \begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} \right\rangle_\kappa := xx' + yy' + \frac{zz'}{\kappa}.$$

In the case $\kappa = 1$, this is the usual Euclidean scalar product. If $\kappa = -1$, then the symmetric bilinear form is not degenerate, but indefinite. We call $\langle \cdot, \cdot \rangle_{-1}$ the ***Minkowski scalar product*** on $\mathbb{R}^3$. It plays an important role in Einstein's special relativity theory. We call the set of all vectors of "vanishing length" the ***light cone***

$$\left\{ X \in \mathbb{R}^3 \,\middle|\, \langle X, X \rangle_{-1} = 0 \right\} = \left\{ (x, y, z)^\top \in \mathbb{R}^3 \,\middle|\, z^2 = x^2 + y^2 \right\}.$$

We now define the Riemannian metric on $\mathbb{M}_\kappa$ by restricting the symmetric bilinear form $\langle \cdot, \cdot \rangle_\kappa$ for every point $p \in \mathbb{M}_\kappa$ to $T_p\mathbb{M}_\kappa$. The construction is thus similar to that of the first fundamental form, except that we have replaced the usual Euclidean scalar product on $\mathbb{R}^3$ by $\langle \cdot, \cdot \rangle_\kappa$.

In the case $\kappa = 0$, one could complain that we need to divide by 0 in the definition of $\langle \cdot, \cdot \rangle_0$, and that the definition is therefore not reasonable. But every tangent plane of $\mathbb{M}_0$ equals $\mathbb{R}^2 \times \{0\}$, i.e. the coefficient of the zz'-term does not play a role anyway. We could therefore without worry replace $\langle\cdot,\cdot\rangle_0$ by the usual Euclidean scalar product without changing the Riemannian metric induced on $\mathbb{M}_0$. It is simply the usual Euclidean metric on the plane.

Since for $\kappa < 0$ the bilinear form $\langle\cdot,\cdot\rangle_\kappa$ is no longer positive definite, it is a priori not clear that the restrictions to the tangent planes of $\mathbb{M}_\kappa$ are positive definite. They need to have this property if we want to obtain a Riemannian metric. To check that at least the restrictions of $\langle\cdot,\cdot\rangle_\kappa$ to the tangent planes are positive definite, we parametrise $\mathbb{M}_\kappa$ as follows:

$$F_\kappa : \mathbb{R}\times\mathbb{R} \to \mathbb{R}^3, \quad F_\kappa(r,\varphi) := \begin{pmatrix} \mathfrak{s}_\kappa(r)\cos(\varphi) \\ \mathfrak{s}_\kappa(r)\sin(\varphi) \\ \mathfrak{c}_\kappa(r) \end{pmatrix}.$$

Here $\mathfrak{c}_\kappa$ and $\mathfrak{s}_\kappa$ are the generalised sine and cosine functions defined in example 4.8.4. Using (4.17) it is easily seen that the image of F_κ is exactly $\mathbb{M}_\kappa$, more precisely

$$F_\kappa(\mathbb{R}\times\mathbb{R}) = F_\kappa([0,\pi/\sqrt{\kappa}]\times[0,2\pi)) = \mathbb{M}_\kappa$$

in the case $\kappa > 0$ and

$$F_\kappa(\mathbb{R}\times\mathbb{R}) = F_\kappa([0,\infty)\times[0,2\pi)) = \mathbb{M}_\kappa$$

in the case $\kappa \leq 0$. Using (4.18) and (4.19) we immediately get the partial derivatives of F_κ:

$$\frac{\partial F_\kappa}{\partial r}(r,\varphi) = \begin{pmatrix} \mathfrak{c}_\kappa(r)\cos(\varphi) \\ \mathfrak{c}_\kappa(r)\sin(\varphi) \\ -\kappa\mathfrak{s}_\kappa(r) \end{pmatrix}, \quad \frac{\partial F_\kappa}{\partial \varphi}(r,\varphi) = \begin{pmatrix} -\mathfrak{s}_\kappa(r)\sin(\varphi) \\ \mathfrak{s}_\kappa(r)\cos(\varphi) \\ 0 \end{pmatrix}.$$

The two partial derivatives are linearly independent for $r \in (0,\pi/\sqrt{\kappa})$ and $r \in (0,\infty)$. Restriction of F_κ to suitable domains therefore gives us local parametrisations cf. the $\mathbb{M}_\kappa$ except for the points $(0,0,1)^\top$ and, in the case $\kappa > 0$, $(0,0,-1)^\top$. At those two special points the tangent plane is exactly the x–y plane and a restriction of $\langle\cdot,\cdot\rangle_\kappa$ gives the usual Euclidean scalar product, and is thus positive definite. For the other points we calculate the coefficients g_{ij} of our restriction with respect to the local parametrisation F_κ, e.g.

$$\begin{aligned}\left\langle \frac{\partial F_\kappa}{\partial r}(r,\varphi), \frac{\partial F_\kappa}{\partial r}(r,\varphi) \right\rangle_\kappa &= \mathfrak{c}_\kappa(r)^2\cos(\varphi)^2 + \mathfrak{c}_\kappa(r)^2\sin(\varphi)^2 + \frac{1}{\kappa}\kappa^2\mathfrak{s}_\kappa(r)^2 \\ &= \mathfrak{c}_\kappa(r)^2 + \kappa\mathfrak{s}_\kappa(r)^2 = 1.\end{aligned}$$

The other components are obtained in a similar way:

$$\left(g_{ij}(r,\varphi)\right)_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & \mathfrak{s}_\kappa(r)^2 \end{pmatrix}. \tag{4.20}$$

This matrix is positive definite for $r \in (0, \pi/\sqrt{\kappa})$ and $r \in (0, \infty)$. Therefore we really have a Riemannian metric on $\mathbb{M}_\kappa$.

Definition 4.9.1 The regular surface $\mathbb{M}_{-1}$ together with the Riemannian metric defined via the restriction of $\langle \cdot, \cdot \rangle_{-1}$, is called the ***hyperbolic plane***.

The special form of the metric in (4.20) shows that F_κ gave us a parametrisation in geodesic polar coordinates at the point $(0,0,1)^\top$. By lemma 4.6.10 the Gauss curvature is now given by

$$K = -\frac{\ddot{\mathfrak{s}}_\kappa(r)}{\mathfrak{s}_\kappa(r)} = \kappa.$$

In particular, the hyperbolic plane has constant Gauss curvature -1. Further, the curves $r \mapsto F_\kappa(r, \varphi)$ are the geodesics parametrised by arc-length that begin at $(0,0,1)^\top$. The traces of these geodesics have a particularly simple geometric characterisation. They are exactly the intersection of the surface $\mathbb{M}_\kappa$ with the plane through the origin, through $(0,0,1)^\top$ and through $(\cos(\varphi), \sin(\varphi), 0)^\top$. In the case of the sphere $\mathbb{M}_1$ this gives the great circles through the "north pole" $(0,0,1)^\top$. In the case of the plane we get the straight lines through this point. In the case of the hyperbolic plane we obtain hyperbolas. What do the other geodesics look like, those that do not pass through $(0,0,1)^\top$?

To understand this, we will use isometries to map the geodesics through $(0,0,1)^\top$ to other geodesics. To do so we need to obtain enough isometries. We investigate which linear maps on $\mathbb{R}^3$ become isometries after a restriction to $\mathbb{M}_\kappa$. For this purpose let $L \in \mathrm{GL}(3)$. Let us first consider the case $\kappa \neq 0$. If L preserves the symmetric bilinear form $\langle \cdot, \cdot \rangle_\kappa$, i.e.

$$\langle LX, LY \rangle_\kappa = \langle X, Y \rangle_\kappa$$

for all $X, Y \in \mathbb{R}^3$, then, in particular, $\widehat{\mathbb{M}}_\kappa$ is mapped to itself and for every $p \in \widehat{\mathbb{M}}_\kappa$ the map $d_pL = L|_{T_p\widehat{\mathbb{M}}_\kappa} : T_p\widehat{\mathbb{M}}_\kappa \to T_{Lp}\widehat{\mathbb{M}}_\kappa$ is a linear isometry. However, in the case $\kappa < 0$ it can happen that the two sheets of the hyperboloid are interchanged. To prevent this we additionally require that $(0,0,1)^\top$ is mapped back to the upper sheet, i.e. the third component of the image vector must be positive. Writing

$$L = \begin{pmatrix} L_{11} & L_{12} & L_{13} \\ L_{21} & L_{22} & L_{23} \\ L_{31} & L_{32} & L_{33} \end{pmatrix},$$

we see that $L_{33} > 0$. The other points of the upper sheet will for reasons of continuity be mapped to the upper sheet as well:

$$L(\mathbb{M}_\kappa) = \mathbb{M}_\kappa.$$

In the case $\kappa = 0$, the vectors of the form $(x, y, 1)^\top$ must be mapped to vectors whose third component is also equal to 1. This means precisely that $L_{31} = L_{32} = 0$ and $L_{33} = 1$. Further, the Euclidean map must be preserved in the x–y plane for the maps to be isometries. This means that

$$\begin{pmatrix} L_{11} & L_{12} \\ L_{21} & L_{22} \end{pmatrix} \in \mathrm{O}(2).$$

Summarising, we can say that we have already found rather large groups of isometries on $\mathbb{M}_\kappa$, i.e.

$$G_\kappa := \begin{cases} \{L \in \mathrm{GL}(3) \mid \langle LX, LY\rangle_\kappa = \langle X, Y\rangle_\kappa \text{ and } L_{33} > 0\}, & \kappa < 0, \\ \{L \in \mathrm{GL}(3) \mid L_{31} = L_{32} = 0, L_{33} = 1, (L_{ij})_{i,j=1,2} \in \mathrm{O}(2)\}, & \kappa = 0, \\ \{L \in \mathrm{GL}(3) \mid \langle LX, LY\rangle_\kappa = \langle X, Y\rangle_\kappa\}, & \kappa > 0. \end{cases}$$

For $\kappa = 1$ we have $G_1 = \mathrm{O}(3)$. In the case $\kappa = 0$, the group G_0 is isomorphic to the Euclidean group $\mathrm{E}(2)$, see definition 1.2.1. Indeed, $L \in G_0$ maps the vector $(x, y, 1)^\top$ to $(L_{11}x + L_{12}y + L_{13}, L_{21}x + L_{22}y + L_{23}, 1)^\top$, i.e. L acts like a Euclidean motion $F_{A,b}$ with $A = (L_{ij})_{i,j=1,2}$ and translational part $b = (L_{13}, L_{23})^\top$.

The elements of the group G_{-1} are called the ***time-preserving Lorentz transformations*** or ***orthochronous Lorentz transformations***, a terminology that comes from relativity theory.

For every κ, the group G_κ contains the rotations around the z-axis:

$$\begin{pmatrix} \cos(\varphi) & -\sin(\varphi) & 0 \\ \sin(\varphi) & \cos(\varphi) & 0 \\ 0 & 0 & 1 \end{pmatrix} \in G_\kappa.$$

Hence every point from $\mathbb{M}_\kappa$ can be moved into the x–z plane by an isometry, i.e. to a point of the form $(\mathfrak{s}_\kappa(r), 0, \mathfrak{c}_\kappa(r))^\top$, without moving the point $(0, 0, 1)^\top$ in this process.

For such a point $(\mathfrak{s}_\kappa(r), 0, \mathfrak{c}_\kappa(r))^\top$ we consider the linear map

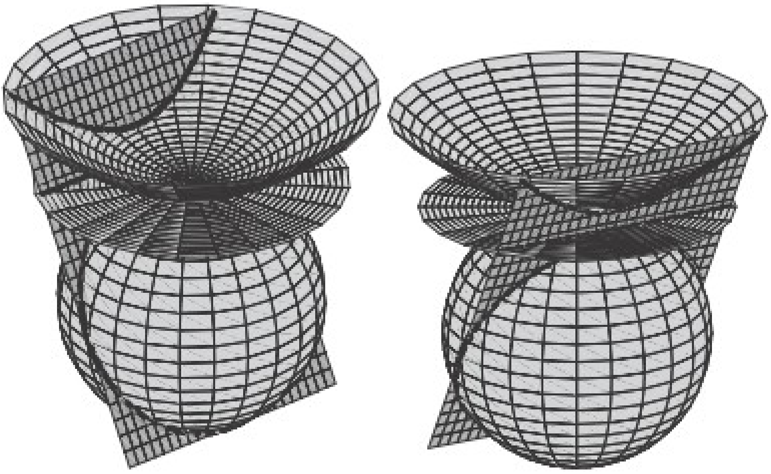
$$L := \begin{pmatrix} -\mathfrak{c}_\kappa(r) & 0 & \mathfrak{s}_\kappa(r) \\ 0 & 1 & 0 \\ \kappa\,\mathfrak{s}_\kappa(r) & 0 & \mathfrak{c}_\kappa(r) \end{pmatrix} \in G_\kappa. \tag{4.21}$$

This L interchanges the two points $(\mathfrak{s}_\kappa(r), 0, \mathfrak{c}_\kappa(r))^\top$ and $(0, 0, 1)^\top$. Altogether we see that *every* point from $\mathbb{M}_\kappa$ can be mapped to the point $(0, 0, 1)^\top$ by a suitable isometry. We say that the isometry group *acts transitively* on $\mathbb{M}_\kappa$. Loosely one could say that $\mathbb{M}_\kappa$ with the Riemannian metric that we constructed is a surface with a very high symmetry.

To come back to our discussion of geodesics, for an arbitrary geodesic through a point $p \in \mathbb{M}_\kappa$ we can find an isometry $L \in G_\kappa$ which maps p to $(0, 0, 1)^\top$ and the geodesic to the intersection of $\mathbb{M}_\kappa$ with a two-dimensional subspace E of $\mathbb{R}^3$. As L is a linear map on $\mathbb{R}^3$, we know that $L^{-1}(E)$ is a two-dimensional subspace of $\mathbb{R}^3$ as well. Generally it no longer contains the point $(0,0,1)^\top$, but instead contains the point p. This is summarised in the following theorem:

Theorem 4.9.2 *The traces of geodesics of $\mathbb{M}_\kappa$ with the Riemannian metric defined by the restriction of $\langle\cdot,\cdot\rangle_\kappa$ are exactly the (non-empty) intersections of $\mathbb{M}_\kappa$ with the two-dimensional subspaces of $\mathbb{R}^3$.*

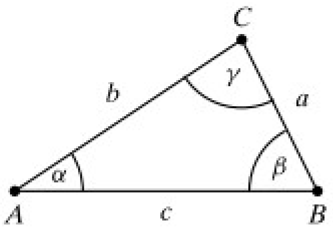
In the case $\kappa = 1$ these are the great circles on S^2, in the case $\kappa = 0$ they are the straight lines in the plane and in the case $\kappa = -1$ we obtain hyperbolas.



Exercise 4.31 Show that G_κ already contains all isometries of $\mathbb{M}_\kappa$.

Hint First use the exponential map to show that for $p \in \mathbb{M}_\kappa$ an isometry $f : \mathbb{M}_\kappa \to \mathbb{M}_\kappa$ is already uniquely determined by the image point $f(p)$ and the differential $d_p f : T_p\mathbb{M}_\kappa \to T_{f(p)}\mathbb{M}_\kappa$.

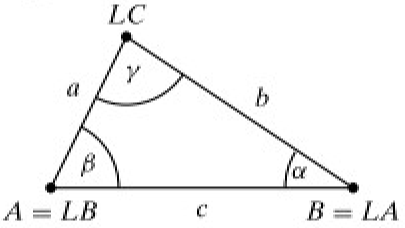
We now begin to derive the trigonometric theorems for $\mathbb{M}_\kappa$. For this purpose we consider a ***geodesic triangle*** on $\mathbb{M}_\kappa$, i.e. three points $A, B, C \in \mathbb{M}_\kappa$, which are connected by geodesics of length a, b, c. We will denote the interior angles at the vertices by α, β, γ. We will in the following always assume that the geodesic triangles are not degenerate, i.e. the lengths of the sides are positive and in the case $\kappa > 0$ smaller than $\pi/\sqrt{\kappa}$ and the angles are in $(0, \pi)$.



We want to find relations between the angles and the lengths of sides. As isometries do not change angles or the lengths of sides, we can first use an isometry to map the point A to $(0,0,1)^\top$ and then rotate B into the x–z plane. Without loss of generality we therefore have

$$A = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad B = \begin{pmatrix} \mathfrak{s}_\kappa(c) \\ 0 \\ \mathfrak{c}_\kappa(c) \end{pmatrix}, \quad C = \begin{pmatrix} \mathfrak{s}_\kappa(b)\cos(\alpha) \\ \mathfrak{s}_\kappa(b)\sin(\alpha) \\ \mathfrak{c}_\kappa(b) \end{pmatrix}.$$

We apply isometry L from (4.21), which interchanges points A and B, with $r = c$ to the entire triangle.



As the side from LC to LB has length a and the angle at A is β, we have

$$LC = \begin{pmatrix} \mathfrak{s}_\kappa(a)\cos(\beta) \\ \mathfrak{s}_\kappa(a)\sin(\beta) \\ \mathfrak{c}_\kappa(a) \end{pmatrix}. \tag{4.22}$$

On the other hand, we calculate

$$\begin{aligned} LC &= \begin{pmatrix} -\mathfrak{c}_\kappa(c) & 0 & \mathfrak{s}_\kappa(c) \\ 0 & 1 & 0 \\ \kappa\mathfrak{s}_\kappa(c) & 0 & \mathfrak{c}_\kappa(c) \end{pmatrix} \cdot \begin{pmatrix} \mathfrak{s}_\kappa(b)\cos(\alpha) \\ \mathfrak{s}_\kappa(b)\sin(\alpha) \\ \mathfrak{c}_\kappa(b) \end{pmatrix} \\ &= \begin{pmatrix} -\mathfrak{c}_\kappa(c)\mathfrak{s}_\kappa(b)\cos(\alpha) + \mathfrak{s}_\kappa(c)\mathfrak{c}_\kappa(b) \\ \mathfrak{s}_\kappa(b)\sin(\alpha) \\ \kappa\mathfrak{s}_\kappa(c)\mathfrak{s}_\kappa(b)\cos(\alpha) + \mathfrak{c}_\kappa(c)\mathfrak{c}_\kappa(b) \end{pmatrix}. \end{aligned} \tag{4.23}$$

We compare the components in (4.22) and (4.23) and obtain

$$\mathfrak{s}_\kappa(a)\cos(\beta) = -\mathfrak{c}_\kappa(c)\mathfrak{s}_\kappa(b)\cos(\alpha) + \mathfrak{s}_\kappa(c)\mathfrak{c}_\kappa(b), \tag{4.24}$$

$$\mathfrak{s}_\kappa(a)\sin(\beta) = \mathfrak{s}_\kappa(b)\sin(\alpha), \tag{4.25}$$

$$\mathfrak{c}_\kappa(a) = \kappa\mathfrak{s}_\kappa(c)\mathfrak{s}_\kappa(b)\cos(\alpha) + \mathfrak{c}_\kappa(b)\mathfrak{c}_\kappa(c). \tag{4.26}$$

Equation 4.25 gives the *sine rule*

$$\frac{\mathfrak{s}_\kappa(a)}{\sin(\alpha)} = \frac{\mathfrak{s}_\kappa(b)}{\sin(\beta)},$$

and (4.26) is called the *cosine rule for sides*. Multiplying (4.24) by $\cos(\alpha)$ and (4.25) by $\sin(\alpha)$ and subtracting the resulting equations one from the other gives

$$\begin{aligned}&\mathfrak{s}_\kappa(a)\,(\cos(\alpha)\cos(\beta)-\sin(\alpha)\sin(\beta))\\&\quad=-\mathfrak{c}_\kappa(c)\mathfrak{s}_\kappa(b)\cos(\alpha)^2+\mathfrak{s}_\kappa(c)\mathfrak{c}_\kappa(b)\cos(\alpha)-\mathfrak{s}_\kappa(b)\sin(\alpha)^2.\end{aligned}\tag{4.27}$$

Interchanging the roles of b and c in (4.24) (i.e. considering triangle ABC instead of ACB) we obtain

$$\mathfrak{s}_\kappa(a)\cos(\gamma)=-\mathfrak{c}_\kappa(b)\mathfrak{s}_\kappa(c)\cos(\alpha)+\mathfrak{s}_\kappa(b)\mathfrak{c}_\kappa(c).\tag{4.28}$$

We substitute (4.28) into (4.27) and finally use the sine rule:

$$\begin{aligned}&\mathfrak{s}_\kappa(a)\,(\cos(\alpha)\cos(\beta)-\sin(\alpha)\sin(\beta))\\&\quad=-\mathfrak{c}_\kappa(c)\mathfrak{s}_\kappa(b)\cos(\alpha)^2-\mathfrak{s}_\kappa(a)\cos(\gamma)+\mathfrak{s}_\kappa(b)\mathfrak{c}_\kappa(c)-\mathfrak{s}_\kappa(b)\sin(\alpha)^2\\&\quad=\mathfrak{s}_\kappa(b)\mathfrak{c}_\kappa(c)\sin(\alpha)^2-\mathfrak{s}_\kappa(a)\cos(\gamma)-\mathfrak{s}_\kappa(b)\sin(\alpha)^2\\&\quad=\mathfrak{s}_\kappa(a)\mathfrak{c}_\kappa(c)\sin(\alpha)\sin(\beta)-\mathfrak{s}_\kappa(a)\cos(\gamma)-\mathfrak{s}_\kappa(a)\sin(\alpha)\sin(\beta).\end{aligned}$$

We divide this equation by $\mathfrak{s}_\kappa(a)$, add $\sin(\alpha)\sin(\beta)$ on both sides and obtain

$$\cos(\alpha)\cos(\beta)=\mathfrak{c}_\kappa(c)\sin(\alpha)\sin(\beta)-\cos(\gamma).$$

This is the *cosine rule for angles*. We summarise these rules in the following theorem:

Theorem 4.9.3 (Spherical and hyperbolic trigonometry) *Let ABC be a geodesic triangle with side-lengths a, b, c and interior angles α, β, γ on $\mathbb{M}_\kappa$. Then the following hold:*

(i) *the sine rule:*

$$\frac{\mathfrak{s}_\kappa(a)}{\sin(\alpha)}=\frac{\mathfrak{s}_\kappa(b)}{\sin(\beta)}=\frac{\mathfrak{s}_\kappa(c)}{\sin(\gamma)};$$

(ii) *the cosine rule for sides:*

$$\begin{aligned}\mathfrak{c}_\kappa(a)&=\mathfrak{c}_\kappa(b)\mathfrak{c}_\kappa(c)+\kappa\mathfrak{s}_\kappa(b)\mathfrak{s}_\kappa(c)\cos(\alpha),\\\mathfrak{c}_\kappa(b)&=\mathfrak{c}_\kappa(a)\mathfrak{c}_\kappa(c)+\kappa\mathfrak{s}_\kappa(a)\mathfrak{s}_\kappa(c)\cos(\beta),\\\mathfrak{c}_\kappa(c)&=\mathfrak{c}_\kappa(a)\mathfrak{c}_\kappa(b)+\kappa\mathfrak{s}_\kappa(a)\mathfrak{s}_\kappa(b)\cos(\gamma);\end{aligned}$$

(iii) *the cosine rule for angles:*

$$\begin{aligned}\cos(\alpha) &= \mathfrak{c}_\kappa(a)\sin(\beta)\sin(\gamma) - \cos(\beta)\cos(\gamma),\\ \cos(\beta) &= \mathfrak{c}_\kappa(b)\sin(\alpha)\sin(\gamma) - \cos(\alpha)\cos(\gamma),\\ \cos(\gamma) &= \mathfrak{c}_\kappa(c)\sin(\alpha)\sin(\beta) - \cos(\alpha)\cos(\beta).\end{aligned}$$

This theorem contains three trigonometric rules for both spherical ($\kappa = 1$) and hyperbolic geometry ($\kappa = -1$). The theorem holds for all $\kappa \in \mathbb{R}$, in particular for $\kappa = 0$. Indeed, the sine rule of Euclidean geometry (theorem 1.2.6) is included in theorem 4.9.3. The cosine rule for sides on the other hand is trivial in the Euclidean case. The cosine rule for angles says that in the case $\kappa = 0$

$$\cos(\gamma) = \sin(\alpha)\sin(\beta) - \cos(\alpha)\cos(\beta) = -\cos(\alpha+\beta) = \cos(\pi - \alpha - \beta),$$

i.e. we obtain theorem 1.2.7 about the sum of interior angles in a Euclidean triangle. In the hyperbolic case $\kappa = -1$ or more generally if $\kappa < 0$, we have for $c > 0$ that $\mathfrak{c}_\kappa(c) > 1$, hence

$$\cos(\gamma) > \sin(\alpha)\sin(\beta) - \cos(\alpha)\cos(\beta) = -\cos(\alpha+\beta) = \cos(\pi - \alpha - \beta)$$

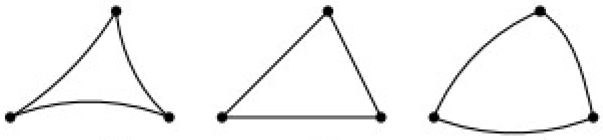
and thus

$$\alpha + \beta + \gamma < \pi.$$

Hyperbolic triangles are therefore "narrow" compared to Euclidean ones. Analogously we see that in the spherical case ($\kappa > 0$)

$$\alpha + \beta + \gamma > \pi.$$

Spherical triangles are "fat".



$\kappa < 0$ $\kappa = 0$ $\kappa > 0$

Exercise 4.32 Use the sine rule for geodesic triangles on $\mathbb{M}_\kappa$ to derive the *height formula*

$$\mathfrak{s}_\kappa(h_c) = \mathfrak{s}_\kappa(b)\sin(\alpha) = \mathfrak{s}_\kappa(a)\sin(\beta).$$

h_c is the height of the triangle with over side $\overline{AB}$.

Exercise 4.33 Derive the cosine rule (theorem 1.2.4) in the Euclidean case $\kappa = 0$ from the sine rule and the cosine rule for angles.

4.10 Cartography

Cartography is the science of geographical maps. Mathematically speaking, we want to study charts of S^2. For simplicity, we will ignore all complications arising from the fact that the earth is better described by a certain rotational ellipsoid than by a sphere. Ideally, one would like to find charts which preserve lengths, angles, and areas up to a scale factor. However, this is not possible since such a chart would be an isometry between a portion of S^2 and a portion of $\mathbb{R}^2$. By Gauss's *Theorema Egregium* no such isometry exists because S^2 has Gauss curvature $K \equiv 1$ while the Euclidean plane has $K \equiv 0$. In the literature on cartography one nevertheless finds statements of the extent that certain maps are length-preserving. This is rather misleading because it means that *some* lengths are preserved, not all.

As we will see it is possible to construct charts that are angle-preserving or area-preserving. A chart is area-preserving if the area element of the sphere expressed in the coordinates u^1, u^2 coincides with the area element of the Euclidean metric of the plane, $dA = du^1\, du^2$. How can we see whether or not a chart is angle-preserving?

Lemma 4.10.1 *Let g and g' be two Euclidean metrics on $\mathbb{R}^n$, $n \geq 2$. Then g and g' define the same angles if and only if there exists a number $c > 0$ such that*

$$g' = c \cdot g.$$

Proof If $g' = c \cdot g$, then for any non-zero vectors $X, Y \in \mathbb{R}^n$ we have

$$\frac{g(X,Y)}{\sqrt{g(X,X)}\sqrt{g(Y,Y)}} = \frac{g'(X,Y)}{\sqrt{g'(X,X)}\sqrt{g'(Y,Y)}},$$

because the factor c cancels. Thus the angles between X and Y are the same for g and for g'.

Conversely, let g and g' define the same angles. Fix a non-zero vector $Y \in \mathbb{R}^n$. For any $X \in \mathbb{R}^n$, not a multiple of Y, consider the triangle with vertices 0, Y and X. Denote the angle at the corner X by η and the one at the corner Y by ξ. It is important that the angles are the same for g and for g'. By the sine rule we have

$$\frac{\|X\|_g}{\|Y\|_g} = \frac{\sin(\xi)}{\sin(\eta)} = \frac{\|X\|_{g'}}{\|Y\|_{g'}},$$

hence

$$g'(X,X) = c \cdot g(X,X)$$

with $c = g'(Y, Y)/g(Y, Y)$. Since the set of vectors X which are not a multiple of Y is dense in $\mathbb{R}^n$ this relation holds for *all* $X \in \mathbb{R}^n$ by continuity. Polarisation implies

$$g'(X, Z) = c \cdot g(X, Z)$$

for all $X, Z \in \mathbb{R}^n$. □

This justifies the following.

Definition 4.10.2 Let S and S' be regular surfaces equipped with Riemannian metrics g and g' respectively. A local diffeomorphism $\Phi : S \to S'$ is called ***angle-preserving*** or ***conformal*** if there exists a positive function $c : S \to \mathbb{R}$ such that

$$\Phi^* g' = c \cdot g.$$

By the previous lemma this means that the angle between $X, Y \in T_pS$ is the same as the angle between $d_p\Phi(X), d_p\Phi(Y) \in T_{\Phi(p)}S$. Note that the *conformal factor* c will, in general, depend on $p \in S$. Since g and Φ^*g' are smooth, c is a smooth function on S.

A local parametrisation (U, F, V) of a regular surface S with Riemannian metric g will be called conformal if it is conformal as a map $F : U \to V$, where U carries the Euclidean metric. In other words, there exists a positive function $c : U \to \mathbb{R}$ such that

$$(g_{ij}(u^1, u^2)) = c(u^1, u^2) \cdot \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

The most common way to specify a location on the surface of the earth is to give its longitude λ and latitude φ. For example, Greenwich (England) has longitude $\lambda = 0$ and latitude $\varphi = 51°28'44'' \approx 0.286 \cdot \pi$. Mathematically, this means that we use the parametrisation introduced in example 3.3.3:

$$F : \left(-\frac{\pi}{2}, \frac{\pi}{2}\right) \times (0, 2\pi) \to \mathbb{R}^3,$$

$$F(\varphi, \lambda) = \begin{pmatrix} \cos(\varphi) \cdot \cos(\lambda) \\ \cos(\varphi) \cdot \sin(\lambda) \\ \sin(\varphi) \end{pmatrix}.$$

The computation of the first fundamental form gave us

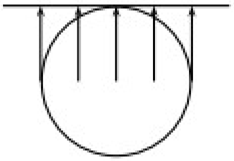
$$\left(g_{ij}(\varphi, \lambda)\right)_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & \cos^2(\varphi) \end{pmatrix}$$

and hence

$$dA = \cos(\varphi)\, d\varphi\, d\lambda.$$

Thus longitude and latitude do not give rise to an area- or angle-preserving map.

Let us instead look at so-called *azimuthal* charts of the sphere. They are obtained by projecting the sphere onto one of its tangent planes. For simplicity, we will always use the tangent plane to the "north pole" $e_3 = (0,0,1)^\top$, but any other point would do equally well. The simplest such chart is the *orthographic projection* or *parallel projection*.



Here we have $U = \{(x,y)^\top \mid x^2+y^2<1\}$, $V = \{(x,y,z)^\top \in \mathbb{R}^3 \mid z>0\}$ and $F(x,y) = (x,y,\sqrt{1-x^2-y^2})^\top$, cf. example 3.1.5. Note that the local parametrisation F is the inverse of the projection. One computes

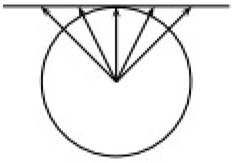
$$(g_{ij}(x,y)) = \frac{1}{1-x^2-y^2}\begin{pmatrix} 1-y^2 & xy \\ xy & 1-x^2 \end{pmatrix}$$

and hence

$$dA = \sqrt{\det(g_{ij}(x,y))}\, dx\, dy = (1-x^2-y^2)^{-1/2}\, dx\, dy.$$

Thus the orthographic projection is neither area- nor angle-preserving. It shows the earth as it is seen from outer space.

The next azimuthal chart is the *gnomonic projection* or *central projection*.

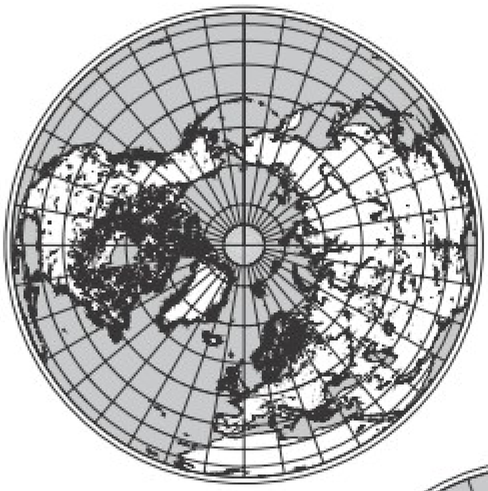


Here we have $U = \mathbb{R}^2$, $V = \{(x,y,z)^\top \in \mathbb{R}^3 \mid z>0\}$, and $F(x,y) = (1/\sqrt{1+x^2+y^2})(x,y,1)^\top$. One computes

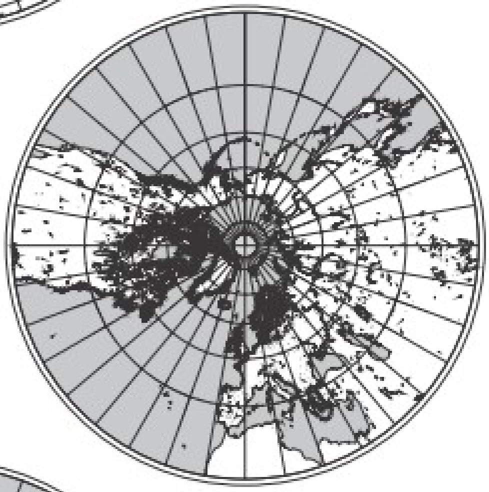
$$(g_{ij}(x,y)) = \frac{1}{(1+x^2+y^2)^2}\begin{pmatrix} 1+y^2 & -xy \\ -xy & 1+x^2 \end{pmatrix}$$

and

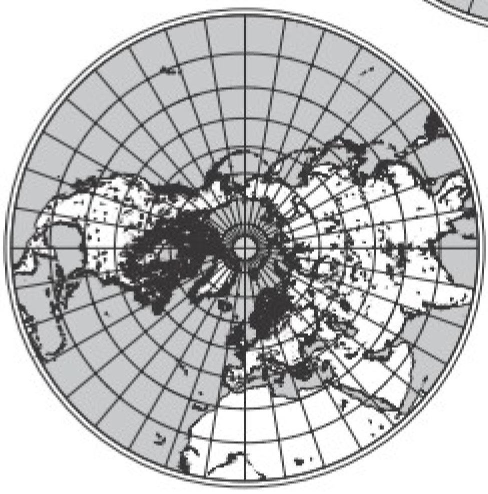
$$dA = (1+x^2+y^2)^{-3/2}\, dx\, dy.$$



orthographic projection



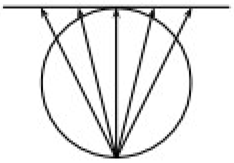
gnomonic projection



stereographic projection

Hence this chart is also neither area- nor angle-preserving but it has the pleasing property that the geodesics on the sphere, the great circles, are represented in the chart by straight lines. This is because a great circle is the intersection of S^2 with a plane E through the origin which is projected to the intersection of E with the tangent plane, a straight line. Thus this type of map is well suited for finding the shortest route from one point to another.

If we change the projection point from the centre of the sphere to the south pole we obtain the *stereographic projection*.



In this case

$$U = \mathbb{R}^2,\ V = \mathbb{R}^3 \setminus \left\{(0,0,-1)^\top\right\},\ F(x,y) = \frac{1}{4+x^2+y^2}(4x, 4y, 4-x^2-y^2)^\top,$$

$$(g_{ij}(x,y)) = \frac{16}{(4+x^2+y^2)^2}\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}$$

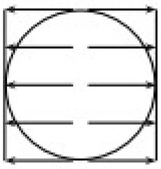
and

$$dA = \frac{16}{(4+x^2+y^2)^2}\,dx\,dy.$$

Thus the stereographic projection is conformal but not area-preserving.

All three projections considered so far satisfy $(g_{ij}(0,0)) = \begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}$. Thus the differential of the local parametrisation is an isometry at $(0,0,)^\top$. The distortion of the map is small near the north pole (or whatever point has been chosen as the projection centre).

To get a map with small distortion in a whole neighbourhood of the equator (or any other great circle) one wraps a cylinder around the equator, projects the sphere onto the cylinder and then unwraps it.



We then have $U = (0,2\pi) \times (-1,1)$, $V = \mathbb{R}^3 \setminus \left\{(x,0,z)^\top \mid x > 0\right\}$, and

$$F(\varphi,h) = \begin{pmatrix}\cos(\varphi)\cdot\sqrt{1-h^2}\\ \sin(\varphi)\cdot\sqrt{1-h^2}\\ h\end{pmatrix}.$$

One computes

$$(g_{ij}(\varphi, h)) = \begin{pmatrix} 1-h^2 & 0 \\ 0 & \dfrac{1}{1-h^2} \end{pmatrix}.$$

Thus this map is not conformal but $dA = d\varphi\, dh$, hence it is area-preserving.

Let us modify this example. We introduce a new parameter x and let the height h be a function of x yet to be determined, i.e.

$$F(\varphi, x) = \begin{pmatrix} \cos(\varphi) \cdot \sqrt{1-h(x)^2} \\ \sin(\varphi) \cdot \sqrt{1-h(x)^2} \\ h(x) \end{pmatrix}.$$

Then we get

$$(g_{ij}(\varphi, x)) = \begin{pmatrix} 1-h(x)^2 & 0 \\ 0 & \dfrac{h'(x)^2}{1-h(x)^2} \end{pmatrix}.$$

We see that we need $h' \neq 0$. We may and will assume that $h' > 0$ because otherwise we may simply replace $h(x)$ by $h(-x)$. In order to get a conformal chart we need

$$1 - h(x)^2 = \frac{h'(x)^2}{1-h(x)^2},$$

i.e.

$$h'(x) = 1 - h(x)^2.$$

The solution to this ordinary differential equation with initial condition $h(0) = 0$ is

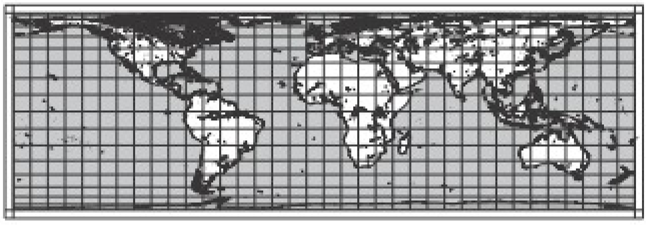
$$h(x) = \tanh(x).$$

The resulting geographical map is known as *Mercator's projection* named after the Flemish geographer Gheert Cremer (1512–1594), who latinised his name to Gerardus Mercator.

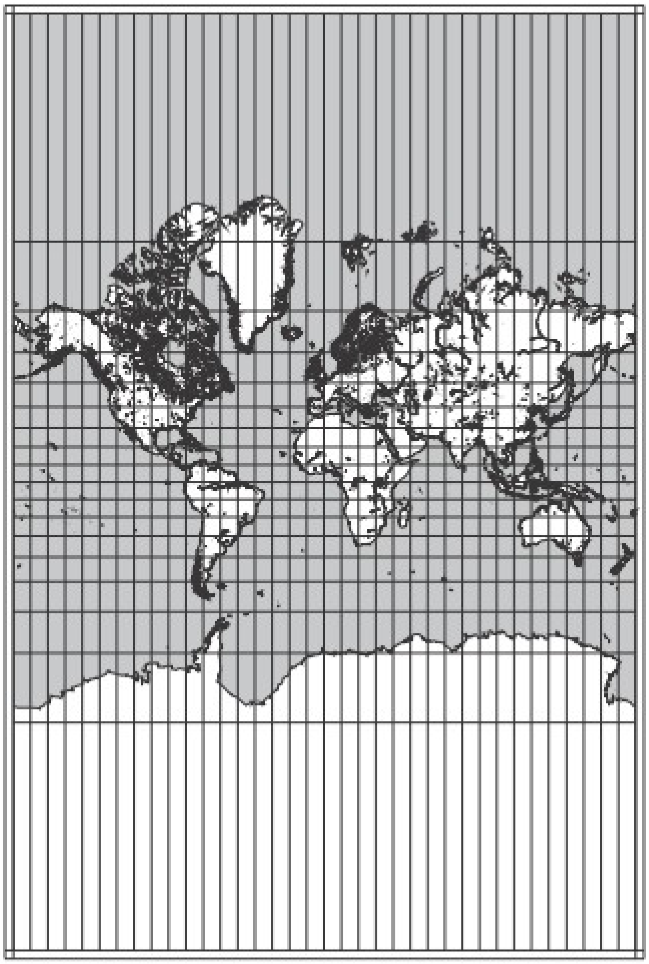
Exercise 4.34 What can you say about the solutions to this ordinary differential equation with other initial values $h(0)$?

There are many more geographical maps. For example, in order to get a good map representation of a neighbourhood of a circle of latitude other than the equator, one can wrap a cone around the sphere along a small circle and then unwrap it. The interested reader should consult a book on cartography such as [28].

Exercise 4.35 Show that there are no geographical maps that are at the same time conformal and area-preserving.



cylindrical equal-area projection



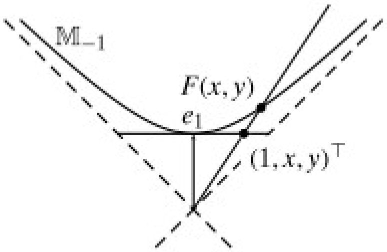
Mercator's projection

4.11 Further models of hyperbolic geometry

We now study charts of the hyperbolic plane. In contrast to the spherical case it is possible to find charts covering the whole hyperbolic plane at once. We will call such charts ***models of hyperbolic geometry***. If (U, F, V) is such a chart with $\mathbb{M}_{-1} \subset V$, then F is a diffeomorphism from U to $\mathbb{M}_{-1}$ and all investigations of hyperbolic geometry can be performed on U using the functions $g_{ij} : U \to \mathbb{R}$ describing the hyperbolic Riemannian metric in this chart. Since the hyperbolic metric was obtained by restricting the Minkowski scalar product of $\mathbb{R}^3$ instead of the Euclidean scalar product, we have

$$g_{ij}\left(u^1, u^2\right) = \left\langle \frac{\partial F}{\partial u^i}\left(u^1, u^2\right), \frac{\partial F}{\partial u^j}\left(u^1, u^2\right)\right\rangle_{-1}.$$

The first chart is obtained by central projection with respect to the origin of the unit disc in $T_{e_1}\mathbb{M}_{-1}$ to $\mathbb{M}_{-1}$.



Expressed as formulae, this becomes, $U = \left\{(x, y)^\top \in \mathbb{R}^2 \mid x^2 + y^2 < 1\right\}$ and

$$F(x, y) = \frac{1}{\sqrt{1 - x^2 - y^2}} \begin{pmatrix} 1 \\ x \\ y \end{pmatrix}. \tag{4.29}$$

This chart is known as the ***Klein model***, as the ***Cayley–Klein model***, as the ***projective model***, and also as the ***Beltrami–Klein model*** of hyperbolic geometry. We compute

$$\frac{\partial F}{\partial x} = \left(1 - x^2 - y^2\right)^{-3/2} \begin{pmatrix} x \\ 1 - y^2 \\ xy \end{pmatrix}, \qquad \frac{\partial F}{\partial y} = \left(1 - x^2 - y^2\right)^{-3/2} \begin{pmatrix} y \\ xy \\ 1 - x^2 \end{pmatrix}$$

and hence

$$g_{11}(x, y) = \left\langle \frac{\partial F}{\partial x}, \frac{\partial F}{\partial x} \right\rangle_{-1}$$

$$= \left(1 - x^2 - y^2\right)^{-3} \cdot \left(-x^2 + \left(1 - y^2\right)^2 + (xy)^2\right)$$
$$= \frac{1 - y^2}{\left(1 - x^2 - y^2\right)^2}$$

and similarly for the other coefficients for the metric. We obtain

$$(g_{ij}(x, y)) = \frac{1}{\left(1 - x^2 - y^2\right)^2} \begin{pmatrix} 1 - y^2 & xy \\ xy & 1 - x^2 \end{pmatrix}.$$

Exercise 4.36 Show that the hyperbolic plane has infinite area.

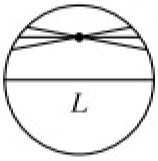
The metric does not look particularly simple in the Klein model but this model has one very pleasing feature: geodesics in $\mathbb{M}_{-1}$ correspond to straight line segments in U. This is clear from the construction of F. The geodesics in $\mathbb{M}_{-1}$ are the intersections of $\mathbb{M}_{-1}$ with planes E containing the origin. Under the central projection this is mapped to the intersection of E with the unit disc in $T_{e_1}\mathbb{M}_{-1}$. The intersection of the two planes E and $T_{e_1}\mathbb{M}_{-1}$ is a straight line.

This allows a simple discussion of the parallel axiom. Keeping the terminology and the notation from the first chapter we now take the hyperbolic plane $\mathbb{M}_{-1}$ as the set of points, the set of "straight lines" will be the set of traces of all geodesics,

$$\mathscr{P} := \mathbb{M}_{-1},$$
$$\mathscr{G} := \{\mathbb{M}_{-1} \cap E |\, E \subset \mathbb{R}^3 \text{ is a two-dimensional subspace}\} - \{\emptyset\}.$$

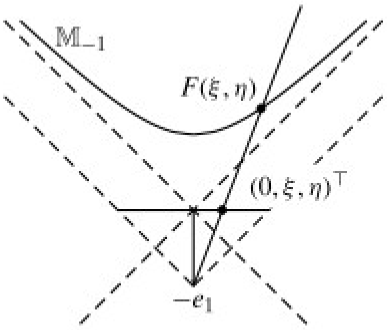
The incidence relation is the usual set-theoretical inclusion. We immediately see that the incidence axioms I_1–I_4 are satisfied. Unlike in spherical geometry, in which geodesics are great circles, there is an obvious useful definition for when one point lies between two others on the hyperbolas in hyperbolic geometry. The validity of the ordering axioms A_1–A_5 is then easy to see. For the definition of congruence of lengths and angles we use isometries as in the discussion of the Cartesian model of Euclidean geometry. This time we use the group G_{-1} of isometries on $\mathbb{M}_{-1}$ instead of the Euclidean group. It is then not difficult to show the validity of the congruence axioms. By theorem 1.1.9 we already know that parallels therefore exist. The completeness axioms can be derived in a way similar to the one used for the Cartesian model.

Only the parallel axiom is not valid, since parallels are not unique. This is easily seen in the Klein model. Given a line segment L in U there is an infinity of line segments not intersecting L but having one point in common.



Hyperbolic geometry shows that the parallel axiom does not follow from the other axioms of Euclidean geometry.

Note that the Klein model is the hyperbolic analogue of the gnomonic chart of the sphere. Also compare their metric coefficients. Now we move on to the hyperbolic analogue of the stereographic projection in spherical geometry. In principle, we only have to change the projection point from the origin to $-e_1$ as in spherical geometry. To get slightly simpler formulae we do not project to $T_{e_1}\mathbb{M}_{-1}$ but to the parallel plane spanned by e_2 and e_3. The difference is only a stretching by a factor of 2.



Set up in this way U is the unit disc as for the Klein model and one easily computes that

$$F(\xi,\eta) = \frac{1}{1-\xi^2-\eta^2}\begin{pmatrix}1+\xi^2+\eta^2\\ 2\xi\\ 2\eta\end{pmatrix}.$$

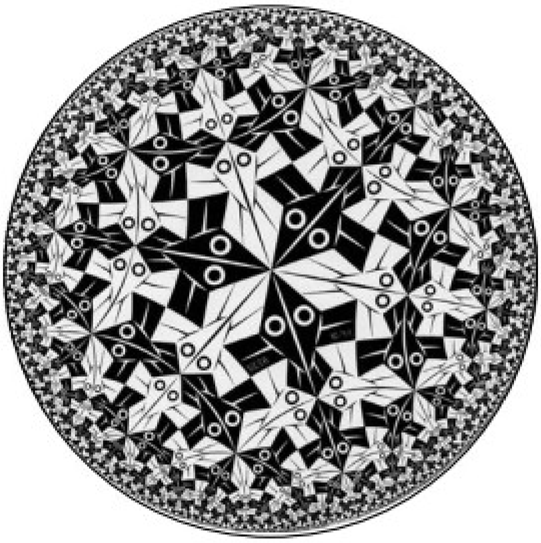
A calculation similar to the one for the Klein model yields

$$(g_{ij}(\xi,\eta)) = \frac{4}{(1-\xi^2-\eta^2)^2}\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}.$$

Thus this model of hyperbolic geometry is conformal just like the stereographic projection. So it comes at no surprise that this model is known as the ***conformal disc model*** and also as the ***Poincaré disc model***. It was popularised by the Dutch artist Maurits Cornelis Escher (1898–1972) in his famous woodcuts such as "Circle Limit I" from 1958.[1]

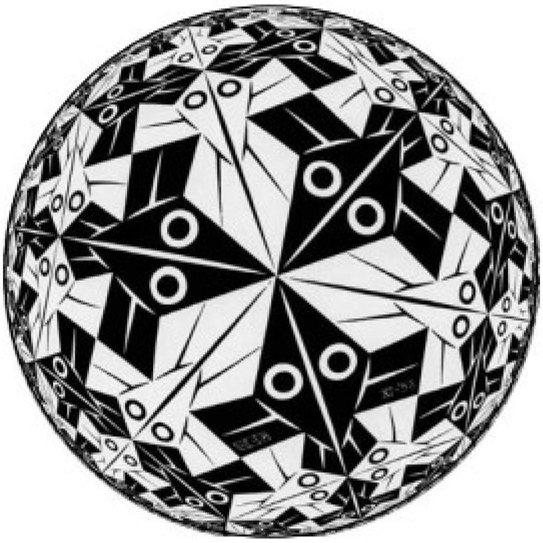
---

[1] M. C. Escher's "Circle Limit I" © 2009 The M. C. Escher Company – Holland. All rights reserved. www.mcescher.com

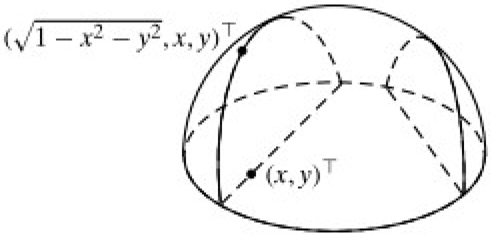


The straight line segments through the centre of the disc correspond to the geodesics of $\mathbb{M}_{-1}$ given by intersections with those planes that contain both the origin and e_1. The other geodesics correspond to circular arcs in the disc meeting its boundary perpendicularly. Escher's woodcut displays some of them. The black fish are all congruent with respect to the hyperbolic metric. In particular, their hyperbolic areas are all the same and similarly for the white fish.

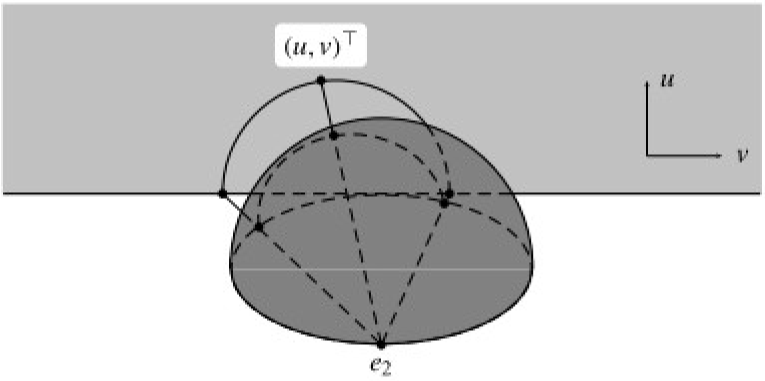
One may wonder what this picture would look like in the Klein model. The circular arcs must be replaced by straight line segments. Indeed, Escher's Circle Limit I transformed to the Klein model looks like this:



There is another interesting and important model. We construct it as follows. We start with the Klein model and do a parallel projection to the upper hemisphere, i.e. the point $(x, y)^\top$ is mapped to $(\sqrt{1-x^2-y^2}, x, y)^\top$. This is the transformation that gave rise to the orthographic chart in cartography. The straight line segments in the disc are mapped to circular arcs meeting the equator of the hemisphere at a right angle.



Now we choose a point on the equator of the hemisphere, say e_2, and perform a stereographic projection with respect to e_2 onto the tangent plane of the sphere at the antipodal point $-e_2$. This maps the upper hemisphere onto the upper half-plane. The spherical arcs are mapped to spherical arcs in the half-plane except for those arcs in the hemisphere that contain e_2. These are projected onto straight lines. Both the spherical arcs and the straight lines meet the boundary of the half-plane at a right angle.



The image of $(\sqrt{1-x^2-y^2}, x, y)^\top$ under this stereographic projection is easily computed to be

$$\begin{pmatrix} u \\ v \end{pmatrix} = \frac{1}{1-x} \begin{pmatrix} 2\sqrt{1-x^2-y^2} \\ 2y \end{pmatrix}.$$

Solving for $(x, y)^\top$ yields

$$\begin{pmatrix} x \\ y \end{pmatrix} = \frac{1}{u^2+v^2+4} \begin{pmatrix} u^2+v^2-4 \\ 4v \end{pmatrix}.$$

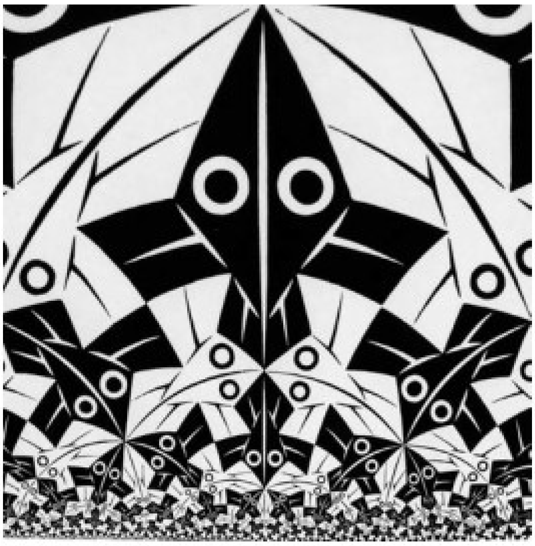
Plugging this into the parametrisation (4.29) of the Klein model gives us the ***Poincaré half-plane model***

$$F(u,v) = \frac{1}{4u}\begin{pmatrix} u^2+v^2+4 \\ u^2+v^2-4 \\ 4v \end{pmatrix}$$

with $U = \{(u,v)^\top \mid u > 0\}$. As before one computes

$$(g_{ij}(u,v)) = \frac{1}{u^2}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

Hence the Poincaré half-plane model is also conformal. Escher's woodcut transformed to this model now looks like this:



Exercise 4.37 The grey region Δ in the Poincaré half-plane model shown in the figure below is a geodesic triangle with vertices at infinity. Compute its area.

7

Curvature of surfaces

In this chapter, we discuss several approaches to the problem of measuring how 'curved' a surface is. Although they use quite different methods, we show that each of the approaches leads to the same geometric object: the *second fundamental form* of a surface. It turns out (see Theorem 10.1.3) that a surface is determined up to an isometry of $\mathbb{R}^3$ by its first and second fundamental forms, just as a unit-speed plane curve is determined up to an isometry of $\mathbb{R}^2$ by its signed curvature.

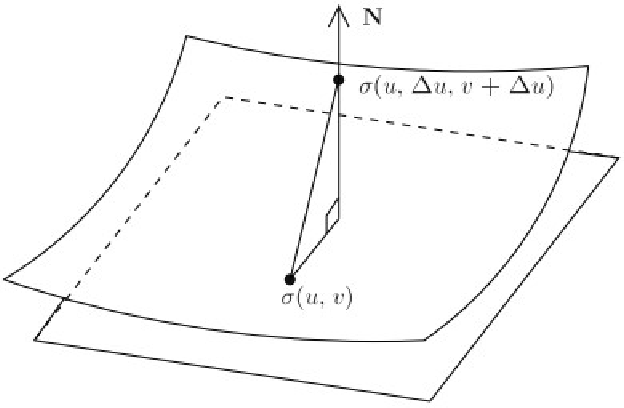
Throughout this chapter we shall work with *oriented* surfaces. Recall from Section 4.5 that every surface *patch* is oriented.

7.1 The second fundamental form

In our first attempt to define the curvature of a surface, we imitate the discussion at the beginning of Section 2.1, which leads to the definition of the curvature of a curve. Suppose then that $\boldsymbol{\sigma}$ is a surface patch in $\mathbb{R}^3$ with standard unit normal $\mathbf{N}$. As the parameters (u, v) of $\boldsymbol{\sigma}$ change to $(u + \Delta u, v + \Delta v)$, the surface moves away from the plane through $\boldsymbol{\sigma}(u, v)$ parallel to the tangent plane by a distance

$$(\boldsymbol{\sigma}(u + \Delta u, v + \Delta v) - \boldsymbol{\sigma}(u, v)) \cdot \mathbf{N}.$$

Andrew Pressley, *Elementary Differential Geometry: Second Edition*,
Springer Undergraduate Mathematics Series, DOI 10.1007/978-1-84882-891-9_7,
© Springer-Verlag London Limited 2010



By the two variable form of Taylor's theorem, $\boldsymbol{\sigma}(u+\Delta u, v+\Delta v) - \boldsymbol{\sigma}(u,v)$ is equal to

$$\boldsymbol{\sigma}_u \Delta u + \boldsymbol{\sigma}_v \Delta v + \frac{1}{2}\left(\boldsymbol{\sigma}_{uu}(\Delta u)^2 + 2\boldsymbol{\sigma}_{uv}\Delta u \Delta v + \boldsymbol{\sigma}_{vv}(\Delta v)^2\right) + \text{ remainder},$$

where (remainder)/$((\Delta u)^2 + (\Delta v)^2)$ tends to zero as $(\Delta u)^2 + (\Delta v)^2$ tends to zero. Now $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ are tangent to the surface, hence perpendicular to $\mathbf{N}$, so the deviation of $\boldsymbol{\sigma}$ from its tangent plane is

$$\frac{1}{2}\left(L(\Delta u)^2 + 2M\Delta u \Delta v + N(\Delta v)^2\right) + \text{remainder}, \tag{7.1}$$

where

$$L = \boldsymbol{\sigma}_{uu} \cdot \mathbf{N}, \quad M = \boldsymbol{\sigma}_{uv} \cdot \mathbf{N}, \quad N = \boldsymbol{\sigma}_{vv} \cdot \mathbf{N}. \tag{7.2}$$

Comparing Eq. 7.2 with Eq. 7.1, we see that the expression

$$L(\Delta u)^2 + 2M\Delta u \Delta v + N(\Delta v)^2$$

is the analogue for the surface of the curvature term $\kappa(\Delta t)^2$ in the case of a curve.

One calls the expression

$$Ldu^2 + 2Mdudv + Ndv^2 \tag{7.3}$$

the *second fundamental form* of the surface patch $\boldsymbol{\sigma}$. It clearly resembles the first fundamental form of a surface patch, and we can make sense of it in the same way, by interpreting du and dv as linear maps as in Section 6.1. Imitating the discussion there, we define a symmetric bilinear form on the tangent plane by

$$\langle \mathbf{v}, \mathbf{w} \rangle = Ldu(\mathbf{v})du(\mathbf{w}) + M(du(\mathbf{v})dv(\mathbf{w}) + du(\mathbf{w})dv(\mathbf{v})) + Ndv(\mathbf{v})dv(\mathbf{w})$$

(cf. Exercise 6.1.3). In the next section, we shall give this form an appealing geometric interpretation, and extend its definition to an arbitrary oriented surface.

Example 7.1.1

Consider the plane

$$\boldsymbol{\sigma}(u,v) = \mathbf{a} + u\mathbf{p} + v\mathbf{q}$$

(see Example 4.1.2). Since $\boldsymbol{\sigma}_u = \mathbf{p}$ and $\boldsymbol{\sigma}_v = \mathbf{q}$ are constant vectors, we have $\boldsymbol{\sigma}_{uu} = \boldsymbol{\sigma}_{uv} = \boldsymbol{\sigma}_{vv} = \mathbf{0}$. Hence, the second fundamental form of a plane is zero.

Example 7.1.2

Consider a surface of revolution (Example 5.3.2)

$$\boldsymbol{\sigma}(u,v) = (f(u)\cos v, f(u)\sin v, g(u));$$

we assume as usual that $f(u) > 0$ for all values of u and that the profile curve $u \mapsto (f(u), 0, g(u))$ is unit-speed, i.e., $\dot{f}^2 + \dot{g}^2 = 1$ (a dot denoting d/du). Then:

$$\begin{aligned}
&\boldsymbol{\sigma}_u = (\dot{f}\cos v, \dot{f}\sin v, \dot{g}), \quad \boldsymbol{\sigma}_v = (-f\sin v, f\cos v, 0),\\
&\quad\therefore \quad \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v = (-f\dot{g}\cos v, -f\dot{g}\sin v, f\dot{f}),\\
&\quad\therefore \quad \parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel = f \quad (\text{since } \dot{f}^2 + \dot{g}^2 = 1),\\
&\therefore \quad \mathbf{N} = \frac{\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v}{\parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel} = (-\dot{g}\cos v, -\dot{g}\sin v, \dot{f}),\\
&\qquad\qquad \boldsymbol{\sigma}_{uu} = (\ddot{f}\cos v, \ddot{f}\sin v, \ddot{g}),\\
&\qquad\qquad \boldsymbol{\sigma}_{uv} = (-\dot{f}\sin v, \dot{f}\cos v, 0),\\
&\qquad\qquad \boldsymbol{\sigma}_{vv} = (-f\cos v, -f\sin v, 0),\\
&\therefore \quad L = \boldsymbol{\sigma}_{uu}\cdot\mathbf{N} = \dot{f}\ddot{g} - \ddot{f}\dot{g}, \ M = \boldsymbol{\sigma}_{uv}\cdot\mathbf{N} = 0, \ N = \boldsymbol{\sigma}_{vv}\cdot\mathbf{N} = f\dot{g},
\end{aligned}$$

so the second fundamental form is

$$(\dot{f}\ddot{g} - \ddot{f}\dot{g})du^2 + f\dot{g}dv^2.$$

For the unit sphere S^2 in latitude–longitude coordinates (Example 4.1.4), $u = \theta$, $v = \varphi$, $f(\theta) = \cos\theta$, $g(\theta) = \sin\theta$, giving the second fundamental form of S^2 as

$$d\theta^2 + \cos^2\theta\, d\varphi^2.$$

Note that this is the same as the *first* fundamental form of S^2 (see Example 6.1.3; the reason for this will appear in Section 8.2).

If the surface is the unit cylinder, we can take $f(u) = 1$, $g(u) = u$ (again, the conditions $f > 0$ and $\dot{f}^2 + \dot{g}^2 = 1$ are satisfied). This gives $L = M = 0, \ N = 1$, so the second fundamental form of the cylinder is dv^2.

EXERCISES

7.1.1 Compute the second fundamental form of the elliptic paraboloid

$$\boldsymbol{\sigma}(u,v) = (u, v, u^2 + v^2).$$

7.1.2 Suppose that the second fundamental form of a surface patch $\boldsymbol{\sigma}$ is zero everywhere. Prove that $\boldsymbol{\sigma}$ is an open subset of a plane. This is the analogue for surfaces of the theorem that a curve with zero curvature everywhere is part of a straight line.

7.1.3 Let a surface patch $\tilde{\boldsymbol{\sigma}}(\tilde{u}, \tilde{v})$ be a reparametrization of a surface patch $\boldsymbol{\sigma}(u,v)$ with reparametrization map $(u,v) = \Phi(\tilde{u}, \tilde{v})$. Prove that

$$\begin{pmatrix} \tilde{L} & \tilde{M} \\ \tilde{M} & \tilde{N} \end{pmatrix} = \pm J^t \begin{pmatrix} L & M \\ M & N \end{pmatrix} J,$$

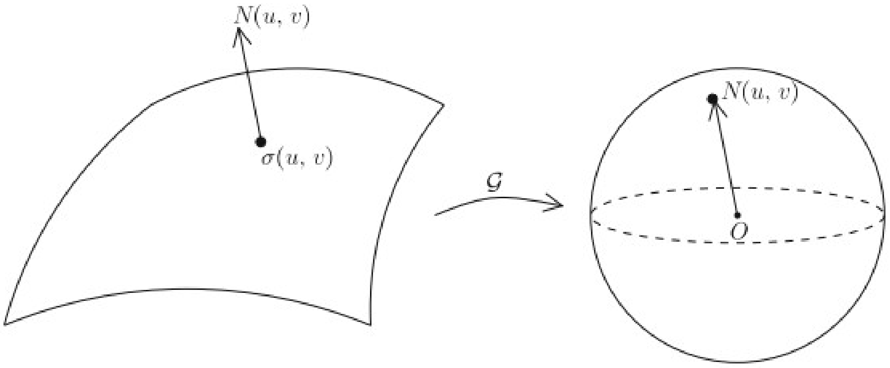
where J is the Jacobian matrix of Φ and we take the plus sign if $\det(J) > 0$ and the minus sign if $\det(J) < 0$. Deduce from Exercise 6.1.4 that the second fundamental form of a surface patch is unchanged by a reparametrization of the patch which preserves its orientation.

7.1.4 What is the effect on the second fundamental form of a surface of applying an isometry of $\mathbb{R}^3$? Or a dilation?

7.2 The Gauss and Weingarten maps

Our second approach to defining the curvature of an oriented surface $\mathcal{S}$ is to consider its unit normal $\mathbf{N}$. The way that $\mathbf{N}$ varies clearly reflects the way in which $\mathcal{S}$ curves: $\mathbf{N}$ varies rapidly near a point at which the surface is highly curved and slowly where the surface is only slightly curved. If $\mathcal{S}$ is a plane, $\mathbf{N}$ is the same at all points of $\mathcal{S}$, i.e., $\mathbf{N}$ is a constant, and the curvature should be zero.

The values of $\mathbf{N}$ at the points of $\mathcal{S}$ are recorded by its *Gauss map* $\mathcal{G}_{\mathcal{S}}$ (or just $\mathcal{G}$ if there is no doubt as to which surface is intended). This is the map from $\mathcal{S}$ to the unit sphere S^2 that assigns to any point $\mathbf{p} \in \mathcal{S}$ the point $\mathbf{N}_{\mathbf{p}} \in S^2$, where $\mathbf{N}_{\mathbf{p}}$ is the unit normal of $\mathcal{S}$ at $\mathbf{p}$.



The rate at which $\mathbf{N}$ varies across $\mathcal{S}$ is measured by the derivative of $\mathcal{G}$:

$$D_{\mathbf{p}}\mathcal{G} : T_{\mathbf{p}}\mathcal{S} \to T_{\mathcal{G}}(\mathbf{p})S^2.$$

Now, the tangent plane at a point $\mathbf{q} \in S^2$ is the plane passing through the origin perpendicular to $\mathbf{q}$. Thus, $T_{\mathcal{G}}(\mathbf{p})S^2$ is the plane through the origin perpendicular to $\mathbf{N}_{\mathbf{p}}$, in other words, $T_{\mathbf{p}}\mathcal{S}$. Thus, the derivative of $\mathcal{G}$ is a linear map from the tangent plane of $\mathcal{S}$ to itself:

$$D_{\mathbf{p}}\mathcal{G} : T_{\mathbf{p}}\mathcal{S} \to T_{\mathbf{p}}\mathcal{S}.$$

Definition 7.2.1

Let $\mathbf{p}$ be a point of a surface $\mathcal{S}$. The *Weingarten map* $\mathcal{W}_{\mathbf{p},\mathcal{S}}$ of $\mathcal{S}$ at $\mathbf{p}$ is defined by

$$\mathcal{W}_{\mathbf{p},\mathcal{S}} = -D_{\mathbf{p}}\mathcal{G}. \tag{7.4}$$

The *second fundamental form* of $\mathcal{S}$ at $\mathbf{p} \in \mathcal{S}$ is the bilinear form on $T_{\mathbf{p}}\mathcal{S}$ given by

$$\langle\!\langle \mathbf{v}, \mathbf{w} \rangle\!\rangle_{\mathbf{p},\mathcal{S}} = \langle \mathcal{W}_{\mathbf{p},\mathcal{S}}(\mathbf{v}), \mathbf{w} \rangle_{\mathbf{p},\mathcal{S}}, \quad \mathbf{v}, \mathbf{w} \in T_{\mathbf{p}}\mathcal{S}.$$

The minus sign is introduced in Eq. 7.4 as a matter of convention (it will reduce the total number of minus signs later). We shall often omit the subscripts $\mathbf{p}$ and $\mathcal{S}$ from the Weingarten map if there is no danger of confusion.

The bilinearity asserted in this definition is easy to check. Let $\mathbf{v}_1, \mathbf{v}_2, \mathbf{w} \in T_{\mathbf{p}}\mathcal{S}$, $\lambda_1, \lambda_2 \in \mathbb{R}$. Then,

$$\begin{aligned}
\langle\!\langle \lambda_1\mathbf{v}_1 + \lambda_2\mathbf{v}_2, \mathbf{w} \rangle\!\rangle &= \langle \mathcal{W}(\lambda_1\mathbf{v}_1 + \lambda_2\mathbf{v}_2), \mathbf{w} \rangle \\
&= \langle \lambda_1\mathcal{W}(\mathbf{v}_1) + \lambda_2\mathcal{W}(\mathbf{v}_2), \mathbf{w} \rangle \\
&= \lambda_1\langle \mathcal{W}(\mathbf{v}_1), \mathbf{w} \rangle + \lambda_2\langle \mathcal{W}(\mathbf{v}_2), \mathbf{w} \rangle \\
&= \lambda_1\langle\!\langle \mathbf{v}_1, \mathbf{w} \rangle\!\rangle + \lambda_2\langle\!\langle \mathbf{v}_2, \mathbf{w} \rangle\!\rangle,
\end{aligned}$$

where we used the linearity of $\mathcal{W}$ in passing from the first line to the second and the bilinearity of $\langle\ ,\ \rangle$ in passing from the second line to the third. This proves that $\langle \mathbf{v}, \mathbf{w}\rangle$ is a linear function of $\mathbf{v}$ for each fixed $\mathbf{w}$. The proof that it is linear in $\mathbf{w}$ for each fixed $\mathbf{v}$ is similar but easier.

Proposition 7.2.2

Let $\mathbf{p}$ be a point of a surface $\mathcal{S}$, let $\boldsymbol{\sigma}(u,v)$ be a surface patch of $\mathcal{S}$ with $\mathbf{p}$ in its image, and let $Ldu^2 + 2Mdudv + Ndv^2$ be the second fundamental form of $\boldsymbol{\sigma}$ defined in Section 7.1. Then, for any $\mathbf{v}, \mathbf{w} \in T_{\mathbf{p}}\mathcal{S}$,

$$\langle \mathbf{v}, \mathbf{w}\rangle = Ldu(\mathbf{v})du(\mathbf{w}) + M(du(\mathbf{v})dv(\mathbf{w}) + du(\mathbf{w})dv(\mathbf{v})) + Ndv(\mathbf{v})dv(\mathbf{w}). \quad (7.5)$$

To prove this we shall need the following lemma, which will also be used elsewhere.

Lemma 7.2.3

Let $\boldsymbol{\sigma}(u,v)$ be a surface patch with standard unit normal $\mathbf{N}(u,v)$. Then,

$$\mathbf{N}_u \cdot \boldsymbol{\sigma}_u = -L, \quad \mathbf{N}_u \cdot \boldsymbol{\sigma}_v = \mathbf{N}_v \cdot \boldsymbol{\sigma}_u = -M, \quad \mathbf{N}_v \cdot \boldsymbol{\sigma}_v = -N,$$

where L, M and N are as defined in Eq. 7.2.

Proof

Since $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ are tangent vectors to the surface patch,

$$\mathbf{N} \cdot \boldsymbol{\sigma}_u = \mathbf{N} \cdot \boldsymbol{\sigma}_v = 0.$$

Differentiating these equations with respect to u and v gives

$$\begin{aligned} \mathbf{N}_u \cdot \boldsymbol{\sigma}_u &= -\mathbf{N} \cdot \boldsymbol{\sigma}_{uu} = -L, \quad & \mathbf{N}_v \cdot \boldsymbol{\sigma}_u &= -\mathbf{N} \cdot \boldsymbol{\sigma}_{uv} = -M, \\ \mathbf{N}_u \cdot \boldsymbol{\sigma}_v &= -\mathbf{N} \cdot \boldsymbol{\sigma}_{uv} = -M, \quad & \mathbf{N}_v \cdot \boldsymbol{\sigma}_v &= -\mathbf{N} \cdot \boldsymbol{\sigma}_{vv} = -N. \end{aligned} \qquad \square$$

Proof 7.2.2 Since both sides of the equation in the statement of the proposition define bilinear forms on $T_{\mathbf{p}}\mathcal{S}$, it suffices to verify that they agree when $\mathbf{v}$ and $\mathbf{w}$ are $\boldsymbol{\sigma}_u$ or $\boldsymbol{\sigma}_v$. Recalling that $du(\boldsymbol{\sigma}_u) = dv(\boldsymbol{\sigma}_v) = 1$, $du(\boldsymbol{\sigma}_v) = dv(\boldsymbol{\sigma}_u) = 0$, we have to prove that

$$\langle \boldsymbol{\sigma}_u, \boldsymbol{\sigma}_u\rangle = L, \quad \langle \boldsymbol{\sigma}_u, \boldsymbol{\sigma}_v\rangle = \langle \boldsymbol{\sigma}_v, \boldsymbol{\sigma}_u\rangle = M, \quad \langle \boldsymbol{\sigma}_v, \boldsymbol{\sigma}_v\rangle = N. \quad (7.6)$$

Let $\boldsymbol{\sigma}(u_0, v_0) = \mathbf{p}$. Then, with the derivatives evaluated at (u_0, v_0),

$$\mathcal{W}(\boldsymbol{\sigma}_u) = -\left.\frac{d}{du}\right|_{u=u_0} \mathcal{G}(\boldsymbol{\sigma}(u, v_0)) = -\left.\frac{d}{du}\right|_{u=u_0} \mathbf{N}(u, v_0) = -\mathbf{N}_u,$$

where $\mathbf{N}$ is the standard unit normal of $\boldsymbol{\sigma}$. Similarly, $\mathcal{W}(\boldsymbol{\sigma}_v) = -\mathbf{N}_v$. Hence,

$$\langle \boldsymbol{\sigma}_u, \boldsymbol{\sigma}_u \rangle = \langle \mathcal{W}(\boldsymbol{\sigma}_u), \boldsymbol{\sigma}_u \rangle = -\mathbf{N}_u \cdot \boldsymbol{\sigma}_u,$$

which is equal to L by Lemma 7.2.3. The other equations in (7.6) are proved similarly. ☐

Since the formula (7.5) for $\langle \mathbf{v}, \mathbf{w} \rangle$ is obviously unchanged when $\mathbf{v}$ and $\mathbf{w}$ are interchanged, we obtain

Corollary 7.2.4

The second fundamental form is a symmetric bilinear form. Equivalently, the Weingarten map is self-adjoint.

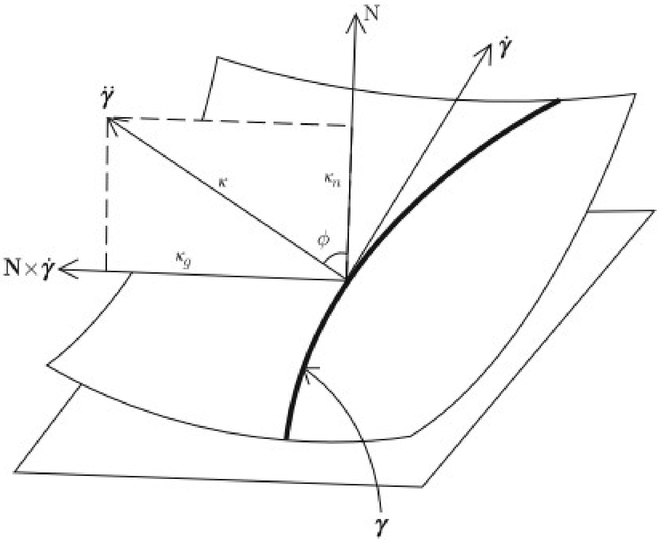
EXERCISES

7.2.1 Calculate the Gauss map $\mathcal{G}$ of the paraboloid $\mathcal{S}$ with equation $z = x^2 + y^2$. What is the image of $\mathcal{G}$?

7.2.2 Show that the Weingarten map changes sign when the orientation of the surface changes.

7.3 Normal and geodesic curvatures

It is obvious that the shape of a surface influences the curvature of curves on the surface. For example, a curve on a plane or a cylinder can have zero curvature everywhere, but this is not possible for curves on a sphere since no segment of a straight line can lie on a sphere. Thus, another natural way to investigate how much a surface curves is to look at the curvature of curves on the surface. We shall see that this leads, once again, to the second fundamental form of the surface.



$\mathbf{N}$
$\dot{\boldsymbol{\gamma}}$
$\ddot{\boldsymbol{\gamma}}$
κ
κ_n
ϕ
κ_g
$\mathbf{N}\times\dot{\boldsymbol{\gamma}}$
$\boldsymbol{\gamma}$

If $\boldsymbol{\gamma}$ is a unit-speed curve on an oriented surface $\mathcal{S}$, then $\dot{\boldsymbol{\gamma}}$ is a unit vector and is, by definition, a tangent vector to $\mathcal{S}$. Hence, $\dot{\boldsymbol{\gamma}}$ is perpendicular to the unit normal $\mathbf{N}$ of $\mathcal{S}$, so $\dot{\boldsymbol{\gamma}}$, $\mathbf{N}$ and $\mathbf{N} \times \dot{\boldsymbol{\gamma}}$ are mutually perpendicular unit vectors. Again since $\boldsymbol{\gamma}$ is unit-speed, $\ddot{\boldsymbol{\gamma}}$ is perpendicular to $\dot{\boldsymbol{\gamma}}$, and hence is a linear combination of $\mathbf{N}$ and $\mathbf{N} \times \dot{\boldsymbol{\gamma}}$:

$$\ddot{\boldsymbol{\gamma}} = \kappa_n \mathbf{N} + \kappa_g \mathbf{N} \times \dot{\boldsymbol{\gamma}}. \tag{7.7}$$

Definition 7.3.1

The scalars κ_n and κ_g in Eq. 7.7 are called the *normal curvature* and the *geodesic curvature* of $\boldsymbol{\gamma}$, respectively.

Note that κ_n and κ_s both change sign when $\mathbf{N}$ is replaced by $-\mathbf{N}$, so on a general (not necessarily orientable) surface only the magnitudes of κ_n and κ_s are well defined.

Proposition 7.3.2

With the above notation, we have

$$\kappa_n = \ddot{\boldsymbol{\gamma}} \cdot \mathbf{N}, \quad \kappa_g = \ddot{\boldsymbol{\gamma}} \cdot (\mathbf{N} \times \dot{\boldsymbol{\gamma}}), \tag{7.8}$$

$$\kappa^2 = \kappa_n^2 + \kappa_g^2, \tag{7.9}$$

$$\kappa_n = \kappa \cos\psi, \kappa_g = \pm\kappa \sin\psi, \tag{7.10}$$

where κ is the curvature of $\boldsymbol{\gamma}$ and ψ is the angle between $\mathbf{N}$ and the principal normal $\mathbf{n}$ of $\boldsymbol{\gamma}$.

Proof

Equations 7.8 and 7.9 follow from Eq. 7.7 and the fact that $\mathbf{N}$ and $\mathbf{N} \times \dot{\boldsymbol{\gamma}}$ are perpendicular unit vectors. The first equation in (7.10) follows from $\ddot{\boldsymbol{\gamma}} = \kappa\mathbf{n}$, and the second then follows from Eq. 7.9. $\square$

If $\boldsymbol{\gamma}$ is regular, but not necessarily unit-speed, we define the geodesic and normal curvatures of $\boldsymbol{\gamma}$ to be those of a unit-speed reparametrization of $\boldsymbol{\gamma}$ (see Exercise 7.3.1). When a unit-speed parameter t is changed to another such parameter $\pm t + c$, where c is a constant, it is clear that $\kappa_n \mapsto \kappa_n$ and $\kappa_g \mapsto \pm\kappa_g$, so κ_n is well defined for any regular curve, while κ_g is well defined up to sign. Equations 7.9 and 7.10 continue to hold if $\boldsymbol{\gamma}$ is any regular curve.

The following proposition is the most important single fact about the normal curvature, and reveals its relation to the second fundamental form $\langle\!\langle\ ,\ \rangle\!\rangle$.

Proposition 7.3.3

If $\boldsymbol{\gamma}$ is a unit-speed curve on an oriented surface $\mathcal{S}$, its normal curvature is given by

$$\kappa_n = \langle\!\langle \dot{\boldsymbol{\gamma}}, \dot{\boldsymbol{\gamma}} \rangle\!\rangle.$$

If $\boldsymbol{\sigma}$ is a surface patch of $\mathcal{S}$ and $\boldsymbol{\gamma}(t) = \boldsymbol{\sigma}(u(t), v(t))$ is a curve in $\boldsymbol{\sigma}$,

$$\kappa_n = L\dot{u}^2 + 2M\dot{u}\dot{v} + N\dot{v}^2$$

in the notation of Section 7.1.

This result means that two curves which *touch* each other at a point $\mathbf{p}$ of a surface (i.e., which intersect at $\mathbf{p}$ and have parallel tangent vectors at $\mathbf{p}$) have the same normal curvature at $\mathbf{p}$.

Proof

Since $\dot{\boldsymbol{\gamma}}$ is a tangent vector to $\mathcal{S}$, $\mathbf{N}.\dot{\boldsymbol{\gamma}} = 0$. Hence, $\mathbf{N} \cdot \ddot{\boldsymbol{\gamma}} = -\dot{\mathbf{N}} \cdot \dot{\boldsymbol{\gamma}}$ so

$$\kappa_n = \mathbf{N} \cdot \ddot{\boldsymbol{\gamma}} = -\dot{\mathbf{N}} \cdot \dot{\boldsymbol{\gamma}} = \langle \mathcal{W}(\dot{\boldsymbol{\gamma}}), \dot{\boldsymbol{\gamma}} \rangle = \langle\!\langle \dot{\boldsymbol{\gamma}}, \dot{\boldsymbol{\gamma}} \rangle\!\rangle,$$

since

$$\dot{\mathbf{N}} = \frac{d}{dt}\mathcal{G}(\boldsymbol{\gamma}(t)) = -\mathcal{W}(\dot{\boldsymbol{\gamma}}).$$

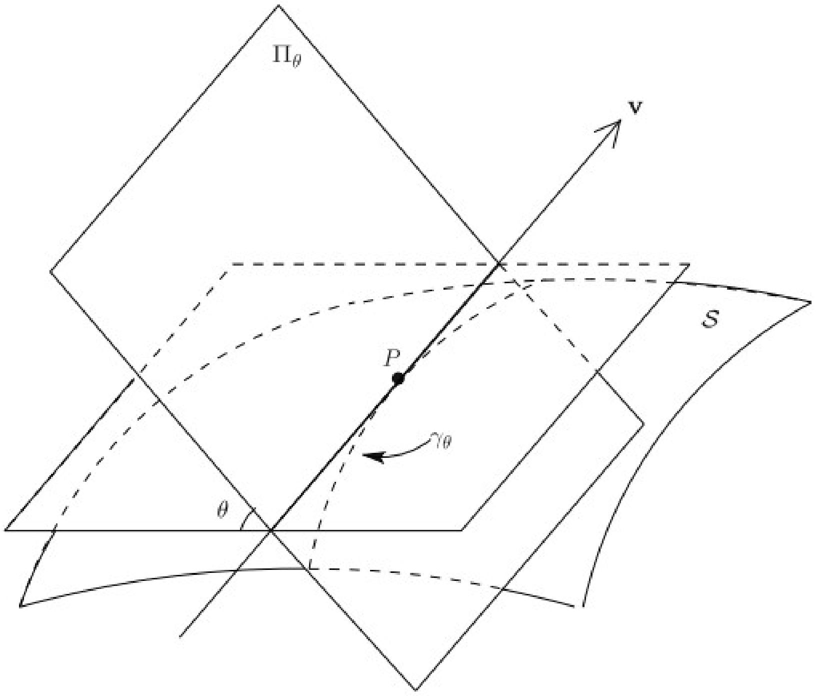
The second part follows from the first and Proposition 7.2.2. $\square$

It turns out that, while the normal curvature depends on the second fundamental form of the surface, the geodesic curvature κ_g depends only on its *first* fundamental form (see Exercise 7.3.4). But we leave further discussion of κ_g to Chapter 9.

Here is a classical application of Proposition 7.3.3. It takes almost as long to state as to prove.

Proposition 7.3.4 (Meusnier's Theorem)

Let $\mathbf{p}$ be a point of a surface $\mathcal{S}$ and let $\mathbf{v}$ be a unit tangent vector to $\mathcal{S}$ at $\mathbf{p}$. Let Π_θ be the plane containing the line through $\mathbf{p}$ parallel to $\mathbf{v}$ and making an angle θ with the tangent plane $T_\mathbf{p}\mathcal{S}$, and assume that Π_θ is not parallel to $T_\mathbf{p}\mathcal{S}$. Suppose that Π_θ intersects $\mathcal{S}$ in a curve with curvature κ_θ. Then, $\kappa_\theta \sin\theta$ is independent of θ.



Proof

Assume that $\boldsymbol{\gamma}_\theta$ is a unit-speed parametrization of the curve of intersection of Π_θ and $\mathcal{S}$. Then, at $\mathbf{p}$, $\dot{\boldsymbol{\gamma}}_\theta = \pm\mathbf{v}$, so $\ddot{\boldsymbol{\gamma}}_\theta$ is perpendicular to $\mathbf{v}$ and is parallel to Π_θ. Thus, in the notation of Proposition 7.3.2, $\psi = \pi/2-\theta$ and so Eq. 7.10 gives

$$\kappa_\theta \sin\theta = \kappa_n.$$

But κ_n depends only on $\mathbf{p}$ and $\mathbf{v}$, and not on θ. ☐

An important special case is that in which $\boldsymbol{\gamma}$ is a *normal section* of the surface, i.e., $\boldsymbol{\gamma}$ is the intersection of the surface with a plane Π that is perpendicular to the tangent plane of the surface at every point of $\boldsymbol{\gamma}$.

Corollary 7.3.5

The curvature κ, normal curvature κ_n and geodesic curvature κ_g of a normal section of a surface are related by

$$\kappa_n = \pm\kappa, \quad \kappa_g = 0.$$

Proof

As in the proof of Proposition 7.3.3, $\kappa_n = \kappa \sin\theta$, where $\theta = \pm\pi/2$ for a normal section. This gives the first equation; the second follows from it and Eq. 7.9. ☐

EXERCISES

7.3.1 Let $\boldsymbol{\gamma}$ be a regular, but not necessarily unit-speed, curve on a surface. Prove that (with the usual notation) the normal and geodesic curvatures of $\boldsymbol{\gamma}$ are

$$\kappa_n = \frac{\langle \dot{\gamma}, \dot{\gamma} \rangle}{\langle \dot{\gamma}, \dot{\gamma} \rangle} \quad \text{and} \quad \kappa_g = \frac{\ddot{\gamma} \cdot (\mathbf{N} \times \dot{\gamma})}{\langle \dot{\gamma}, \dot{\gamma} \rangle^{3/2}}.$$

7.3.2 Show that the normal curvature of any curve on a sphere of radius r is $\pm 1/r$.

7.3.3 Compute the geodesic curvature of any circle on a sphere (not necessarily a great circle).

7.3.4 Show that, if $\boldsymbol{\gamma}(t) = \boldsymbol{\sigma}(u(t), v(t))$ is a unit-speed curve on a surface patch $\boldsymbol{\sigma}$ with first fundamental form $Edu^2 + 2Fdudv + Gdv^2$, the geodesic curvature of $\boldsymbol{\gamma}$ is

$$\kappa_g = (\ddot{v}\dot{u} - \dot{v}\ddot{u})\sqrt{EG - F^2} + A\dot{u}^3 + B\dot{u}^2\dot{v} + C\dot{u}\dot{v}^2 + D\dot{v}^3,$$

where A, B, C and D can be expressed in terms of E, F, G and their derivatives. Find A, B, C, D explicitly when $F = 0$.

7.3.5 Suppose that a unit-speed curve $\boldsymbol{\gamma}$ with curvature $\kappa > 0$ and principal normal $\mathbf{n}$ is a parametrization of the intersection of two oriented surfaces $\mathcal{S}_1$ and $\mathcal{S}_2$ with unit normals $\mathbf{N}_1$ and $\mathbf{N}_2$. Show that, if κ_1 and κ_2 are the normal curvatures of $\boldsymbol{\gamma}$ when viewed as a curve in $\mathcal{S}_1$ and $\mathcal{S}_2$, respectively, then

$$\kappa_1 \mathbf{N}_2 - \kappa_2 \mathbf{N}_1 = \kappa(\mathbf{N}_1 \times \mathbf{N}_2) \times \mathbf{n}.$$

Deduce that, if α is the angle between the two surfaces,

$$\kappa^2 \sin^2 \alpha = \kappa_1^2 + \kappa_2^2 - 2\kappa_1\kappa_2 \cos\alpha.$$

7.3.6 A curve $\boldsymbol{\gamma}$ on a surface $\mathcal{S}$ is called *asymptotic* if its normal curvature is everywhere zero. Show that any straight line on a surface is an asymptotic curve. Show also that a curve $\boldsymbol{\gamma}$ with positive curvature is asymptotic if and only if its binormal $\mathbf{b}$ is parallel to the unit normal of $\mathcal{S}$ at all points of $\boldsymbol{\gamma}$.

7.3.7 Prove that the asymptotic curves on the surface

$$\boldsymbol{\sigma}(u, v) = (u\cos v, u \sin v, \ln u)$$

are given by

$$\ln u = \pm(v + c),$$

where c is an arbitrary constant.

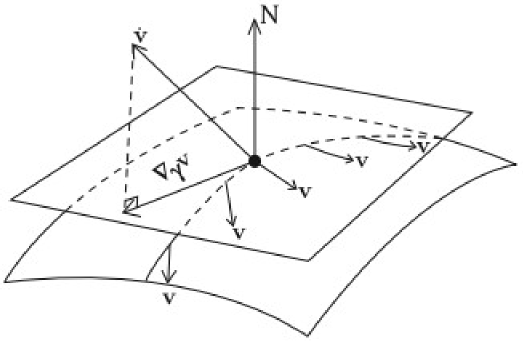
7.4 Parallel transport and covariant derivative

Imagine that there is a road that runs along the Earth's equator and that you are driving along this road at constant speed. The road would appear perfectly straight – you would not have to turn to the right or left to continue along the road. Thus, you would perceive your *velocity* (and not just your speed) as being *constant*. On the other hand, an observer in space would see that your velocity is not constant as you are travelling in a circle rather than in a straight line. The resolution of this apparent paradox is that an observer restricted to the surface of the Earth perceives only the component of the acceleration tangential to the surface. From the point of view of the observer in space, the acceleration vector points towards the centre of the Earth, and so has zero tangential component.

In general, suppose that $\boldsymbol{\gamma}$ is a curve on a surface $\mathcal{S}$ and let $\mathbf{v}$ be a *tangent vector field* along $\boldsymbol{\gamma}$, i.e., a smooth map from an open interval (α, β) to $\mathbb{R}^3$ such that $\mathbf{v}(t) \in T_{\boldsymbol{\gamma}(t)}\mathcal{S}$ for all $t \in (\alpha, \beta)$. To an observer moving along the curve $\boldsymbol{\gamma}$, the perceived rate of change of $\mathbf{v}$ is the tangential component of $\dot{\mathbf{v}}$, i.e., the orthogonal projection of $\dot{\mathbf{v}} = d\mathbf{v}/dt$ onto $T_{\boldsymbol{\gamma}(t)}\mathcal{S}$. If $\mathbf{N}$ is a unit normal to $\boldsymbol{\sigma}$, the component of $\dot{\mathbf{v}}$ perpendicular to the surface is $(\dot{\mathbf{v}} \cdot \mathbf{N})\mathbf{N}$, so the tangential component is

$$\nabla_{\boldsymbol{\gamma}}\mathbf{v} = \dot{\mathbf{v}} - (\dot{\mathbf{v}} \cdot \mathbf{N})\mathbf{N}. \tag{7.11}$$

Note that this is unchanged if $\mathbf{N}$ is replaced by $-\mathbf{N}$, so $\nabla_{\boldsymbol{\gamma}}\mathbf{v}$ is well defined on any surface, orientable or not.



Definition 7.4.1

Let $\boldsymbol{\gamma}$ be a curve on a surface $\mathcal{S}$ and let $\mathbf{v}$ be a tangent vector field along $\boldsymbol{\gamma}$. The *covariant derivative* of $\mathbf{v}$ along $\boldsymbol{\gamma}$ is the orthogonal projection $\nabla_{\boldsymbol{\gamma}}\mathbf{v}$ of $d\mathbf{v}/dt$ onto the tangent plane $T_{\boldsymbol{\gamma}(t)}\mathcal{S}$ at a point $\boldsymbol{\gamma}(t)$.

In particular, an inhabitant of $\mathcal{S}$ would perceive $\mathbf{v}$ as being constant along $\boldsymbol{\gamma}$ if $\nabla_{\boldsymbol{\gamma}}\mathbf{v} = \mathbf{0}$. In this case, $\mathbf{v}$ is sometimes said to be *covariant constant*, but the usual terminology is contained in

Definition 7.4.2

With the notation in Definition 7.4.1, $\mathbf{v}$ is said to be *parallel along* $\boldsymbol{\gamma}$ if $\nabla_{\boldsymbol{\gamma}}\mathbf{v} = \mathbf{0}$ at every point of $\boldsymbol{\gamma}$.

Proposition 7.4.3

A tangent vector field $\mathbf{v}$ is parallel along a curve $\boldsymbol{\gamma}$ on a surface $\mathcal{S}$ if and only if $\dot{\mathbf{v}}$ is perpendicular to the tangent plane of $\mathcal{S}$ at all points of $\boldsymbol{\gamma}$.

8

Gaussian, mean and principal curvatures

In this chapter, we show how to extract geometric information from the second fundamental form of a surface or, equivalently, from its Weingarten map.

8.1 Gaussian and mean curvatures

We start by defining two new measures of the curvature of a surface.

Definition 8.1.1

Let $\mathcal{W}$ be the Weingarten map of an oriented surface $\mathcal{S}$ at a point $\mathbf{p} \in \mathcal{S}$. The Gaussian curvature K and mean curvature H of $\mathcal{S}$ at $\mathbf{p}$ are defined by

$$K = \det(\mathcal{W}), \quad H = \frac{1}{2}\text{trace}(\mathcal{W}).$$

Recall that the determinant and trace of a linear map (such as $\mathcal{W}$) can be computed as the determinant and the sum of the diagonal entries of the matrix of the linear map with respect to any basis (in this case of the tangent plane), and that they depend only on the linear map and not on the choice of basis.

When the sign of the unit normal of $\mathcal{S}$ is changed, the Weingarten map also changes sign (Exercise 7.2.2), thus leaving K unchanged. This implies that the Gaussian curvature is defined for *any* surface $\mathcal{S}$, orientable or not: to define K at a point $\mathbf{p} \in \mathcal{S}$, choose a surface patch $\boldsymbol{\sigma}$ with $\mathbf{p}$ in its image; this is an

Andrew Pressley, *Elementary Differential Geometry: Second Edition*,
Springer Undergraduate Mathematics Series, DOI 10.1007/978-1-84882-891-9_8,
© Springer-Verlag London Limited 2010

oriented surface, which may be used to define K, and the result is independent of the choice of $\boldsymbol{\sigma}$. On the other hand, on a surface that is not necessarily orientable, H is in general only well defined up to sign.

To get explicit formulas for H and K, we work in a surface patch of $\mathcal{S}$. Let $\boldsymbol{\sigma}(u, v)$ be a surface patch with first and second fundamental forms

$$Edu^2 + 2Fdudv + Gdv^2 \quad \text{and} \quad Ldu^2 + 2Mdudv + Ndv^2,$$

respectively. Define symmetric 2×2 matrices $\mathcal{F}_I$ and $\mathcal{F}_{II}$ by

$$\mathcal{F}_I = \begin{pmatrix} E & F \\ F & G \end{pmatrix}, \quad \mathcal{F}_{II} = \begin{pmatrix} L & M \\ M & N \end{pmatrix}.$$

Proposition 8.1.2

Let $\boldsymbol{\sigma}$ be a surface patch of an oriented surface $\mathcal{S}$. Then, with the above notation, the matrix of $\mathcal{W}_{\mathbf{p},\mathcal{S}}$ with respect to the basis $\{\boldsymbol{\sigma}_u, \boldsymbol{\sigma}_v\}$ of $T_{\mathbf{p}}\mathcal{S}$ is $\mathcal{F}_I^{-1}\mathcal{F}_{II}$.

Proof

By the proof of Proposition 7.2.2, $\mathcal{W}(\boldsymbol{\sigma}_u) = -\mathbf{N}_u$ and $\mathcal{W}(\boldsymbol{\sigma}_v) = -\mathbf{N}_v$, so the matrix of $\mathcal{W}$ is $\begin{pmatrix} a & c \\ b & d \end{pmatrix}$, where

$$-\mathbf{N}_u = a\boldsymbol{\sigma}_u + b\boldsymbol{\sigma}_v, \quad -\mathbf{N}_v = c\boldsymbol{\sigma}_u + d\boldsymbol{\sigma}_v.$$

Take the dot product of each of these equations with $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ and use Lemma 7.2.3; this gives

$$\begin{aligned} L &= aE + bF, \qquad & M &= cE + dF, \\ M &= aF + bG, \qquad & N &= cF + dG. \end{aligned}$$

These four scalar equations are equivalent to the single matrix equation

$$\begin{pmatrix} L & M \\ M & N \end{pmatrix} = \begin{pmatrix} E & F \\ F & G \end{pmatrix} \begin{pmatrix} a & c \\ b & d \end{pmatrix}$$
$$\text{i.e.,} \quad \mathcal{F}_{II} = \mathcal{F}_I \begin{pmatrix} a & c \\ b & d \end{pmatrix}.$$

Hence, the matrix of $\mathcal{W}$ with respect to the basis $\{\boldsymbol{\sigma}_u, \boldsymbol{\sigma}_v\}$ is

$$\begin{pmatrix} a & c \\ b & d \end{pmatrix} = \mathcal{F}_I^{-1}\mathcal{F}_{II}.$$

□

Corollary 8.1.3

We have

$$H = \frac{LG - 2MF + NE}{2(EG - F^2)}, \quad K = \frac{LN - M^2}{EG - F^2}.$$

Proof

By Definition 8.1.1,

$$K = \det\left(\mathcal{F}_I^{-1}\mathcal{F}_{II}\right) = \frac{\det(\mathcal{F}_{II})}{\det(\mathcal{F}_I)} = \frac{LN - M^2}{EG - F^2}.$$

To compute H, we need the trace of the matrix

$$\begin{aligned} \mathcal{F}_I^{-1}\mathcal{F}_{II} &= \frac{1}{EG - F^2}\begin{pmatrix} G & -F \\ -F & E \end{pmatrix}\begin{pmatrix} L & M \\ M & N \end{pmatrix} \\ &= \frac{1}{EG - F^2}\begin{pmatrix} LG - MF & MG - NF \\ ME - LF & NE - MF \end{pmatrix}. \end{aligned}$$

Thus,

$$2H = \operatorname{trace}\left(\mathcal{F}_I^{-1}\mathcal{F}_{II}\right) = \frac{LG - 2MF + NE}{EG - F^2}. \qquad \square$$

Example 8.1.4

In Examples 6.1.3 and 7.1.2 we considered the surface of revolution

$$\boldsymbol{\sigma}(u, v) = (f(u)\cos v, f(u)\sin v, g(u)),$$

where we can assume that $f > 0$ and $\dot{f}^2 + \dot{g}^2 = 1$ everywhere (a dot denoting d/du). We found that

$$E = 1,\ F = 0,\ G = f^2,\ \ L = \dot{f}\ddot{g} - \ddot{f}\dot{g},\ M = 0,\ N = f\dot{g}.$$

By Corollary 8.1.3, the Gaussian curvature is

$$K = \frac{LN - M^2}{EG - F^2} = \frac{(\dot{f}\ddot{g} - \ddot{f}\dot{g})f\dot{g}}{f^2}.$$

We can simplify this formula by noting that $\dot{f}^2 + \dot{g}^2 = 1$ implies (by differentiating with respect to u) that $\dot{f}\ddot{f} + \dot{g}\ddot{g} = 0$,

$$\begin{aligned} \therefore \quad (\dot{f}\ddot{g} - \ddot{f}\dot{g})\dot{g} &= -\dot{f}^2\ddot{f} - \ddot{f}\dot{g}^2 = -\ddot{f}(\dot{f}^2 + \dot{g}^2) = -\ddot{f}, \\ \therefore \quad K &= -\frac{\ddot{f}f}{f^2} = -\frac{\ddot{f}}{f}. \end{aligned}$$

We consider some special cases. If $\boldsymbol{\gamma}(u) = (u, 0, 0)$ is the x-axis, the corresponding surface of revolution is the xy-plane; since $f(u) = u$, we have $\dot{f} = 1$, $\ddot{f} = 0$, so $K = 0$. If $\boldsymbol{\gamma}(u) = (1, 0, u)$ is a straight line parallel to the z-axis, the corresponding surface is the unit cylinder; since $f(u) = 1$, $\ddot{f} = 0$, so $K = 0$. Finally, if $\boldsymbol{\gamma}(u) = (\cos u, 0, \sin u)$ is a circle of radius 1, the corresponding surface is the unit sphere; since $f(u) = \cos u$, $\dot{f} = -\sin u$, $\ddot{f} = -\cos u$ so $K = -\ddot{f}/f = -(-\cos u)/\cos u = 1$. Note that in each of these examples the curve $\boldsymbol{\gamma}$ is unit-speed.

Example 8.1.5

For a ruled surface, take a patch

$$\boldsymbol{\sigma}(u, v) = \boldsymbol{\gamma}(u) + v\boldsymbol{\delta}(u),$$

(see Example 5.3.1). Denoting d/du by a dot, we have $\boldsymbol{\sigma}_u = \dot{\boldsymbol{\gamma}} + v\dot{\boldsymbol{\delta}}$, $\boldsymbol{\sigma}_v = \boldsymbol{\delta}$, so

$$\boldsymbol{\sigma}_{uv} = \dot{\boldsymbol{\delta}}, \quad \boldsymbol{\sigma}_{vv} = \mathbf{0}.$$

Hence, if $\mathbf{N} = (\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v)/ \parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel$ is the standard unit normal of $\boldsymbol{\sigma}$, then $M = \boldsymbol{\sigma}_{uv} \cdot \mathbf{N} = \dot{\boldsymbol{\delta}} \cdot \mathbf{N}$ and $N = 0$. So

$$K = \frac{LN - M^2}{EG - F^2} = \frac{-(\dot{\boldsymbol{\delta}} \cdot \mathbf{N})^2}{EG - F^2} \leq 0,$$

i.e., *the Gaussian curvature of a ruled surface is negative or zero.*

Gauss discovered a way to obtain the Gaussian curvature from the Gauss map itself, rather than from its derivative, the Weingarten map. His result is an analogue of Proposition 2.2.3, which shows that, if $\boldsymbol{\gamma}$ is a unit-speed plane curve, its signed curvature $\kappa_s = \dot{\varphi}$, where φ is the angle between its tangent vector $\dot{\boldsymbol{\gamma}}$ and a fixed direction, i.e., the (signed) *curvature is the rate of change of direction of the tangent vector of* $\boldsymbol{\gamma}$ *per unit length.* The 'direction' of the tangent plane to an oriented surface $\mathcal{S}$ is measured by its unit normal $\mathbf{N}$, so we might expect that a measure of the curvature of $\boldsymbol{\sigma}$ is the 'rate of change of $\mathbf{N}$ per unit area'. The values of $\mathbf{N}$ at points of $\mathcal{S}$ are recorded by the Gauss map $\mathcal{G}$, so if R is a small region on $\mathcal{S}$ containing a point $\mathbf{p}$, we should look at the ratio

$$\frac{\text{Area}(\mathcal{G}(R))}{\text{Area}(R)}$$

in the limit as the region R shrinks down to the point $\mathbf{p}$.

To make this idea precise, we work in a surface patch.

Theorem 8.1.6

Let $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ be a surface patch, let $(u_0, v_0) \in U$, and let $\delta > 0$ be such that the closed disc

$$R_\delta = \{(u, v) \in \mathbb{R}^2 \mid (u - u_0)^2 + (v - v_0)^2 \leq \delta^2\}$$

with centre (u_0, v_0) and radius δ is contained in U. Then,

$$\lim_{\delta \to 0} \frac{\mathcal{A}_{\mathbf{N}}(R_\delta)}{\mathcal{A}_{\boldsymbol{\sigma}}(R_\delta)} = |K|,$$

where K is the Gaussian curvature of $\boldsymbol{\sigma}$ at $\boldsymbol{\sigma}(u_0, v_0)$.

Note that a δ with the properties in the statement of the theorem exists because U is open.

Proof

By Definition 6.4.1,

$$\frac{\mathcal{A}_{\mathbf{N}}(R_\delta)}{\mathcal{A}_{\boldsymbol{\sigma}}(R_\delta)} = \frac{\int_{R_\delta} \parallel \mathbf{N}_u \times \mathbf{N}_v \parallel \; dudv}{\int_{R_\delta} \parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel \; dudv}. \tag{8.1}$$

In the notation of the proof of Proposition 8.1.2,

$$\begin{aligned}
\mathbf{N}_u \times \mathbf{N}_v &= (a\boldsymbol{\sigma}_u + b\boldsymbol{\sigma}_v) \times (c\boldsymbol{\sigma}_u + d\boldsymbol{\sigma}_v) \\
&= (ad - bc)\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \\
&= \det(\mathcal{F}_I^{-1}\mathcal{F}_{II})\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \\
&= \frac{\det(\mathcal{F}_{II})}{\det(\mathcal{F}_I)}\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \\
&= \frac{LN - M^2}{EG - F^2}\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \\
&= K\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \quad \text{(by Corollary 8.1.3).}
\end{aligned} \tag{8.2}$$

Substituting in Eq. 8.1, we get

$$\frac{\mathcal{A}_{\mathbf{N}}(R_\delta)}{\mathcal{A}_{\boldsymbol{\sigma}}(R_\delta)} = \frac{\int_{R_\delta} |K| \parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel \; dudv}{\int_{R_\delta} \parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel \; dudv}.$$

Let ϵ be any positive number. Since $K(u, v)$ is a continuous function of (u, v) (see Exercise 8.1.3), we can choose $\delta > 0$ so small that

$$|K(u, v) - K(u_0, v_0)| < \epsilon$$

if $(u, v) \in R_\delta$. Since, for any real numbers a, b, $|a - b| \geq ||a| - |b||$, it follows that $||K(u,v)| - |K(u_0, v_0)|| < \epsilon$ if $(u, v) \in R_\delta$, i.e.,

$$|K(u_0, v_0)| - \epsilon < |K(u,v)| < |K(u_0, v_0)| + \epsilon$$

if $(u, v) \in R_\delta$. Multiplying through by $\| \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \|$ and integrating over R_δ, we get

$$\begin{aligned}(|K(u_0, v_0)| - \epsilon) \int \| \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \| \, du dv &< \int |K(u,v)| \, \| \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \| \, du dv \\ &< (|K(u_0, v_0)| + \epsilon) \int \| \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \| \, du dv, \\ \therefore \quad |K(u_0, v_0)| - \epsilon < \frac{\mathcal{A}_{\mathbf{N}}(R_\delta)}{\mathcal{A}_{\boldsymbol{\sigma}}(R_\delta)} &< |K(u_0, v_0)| + \epsilon \quad \text{(using Eq. 8.1)} \\ \therefore \quad \left| \frac{\mathcal{A}_{\mathbf{N}}(R_\delta)}{\mathcal{A}_{\boldsymbol{\sigma}}(R_\delta)} - |K(u_0, v_0)| \right| &< \epsilon.\end{aligned}$$

This proves the theorem. □

Although this proposition only gives the absolute value of the Gaussian curvature K, the sign can be recovered from the Gauss map if we define the *signed area* of $\mathcal{G}(R)$ to be $\pm \mathcal{A}_{\mathbf{N}}(R)$, where the sign is $+$ or $-$ according to whether $\mathbf{N}_u \times \mathbf{N}_v$ points in the same or the opposite direction as $\mathbf{N}$. By Eq. 8.3, this sign is that of K, so K is the limit of the ratio

$$\frac{\text{Signed area}(\mathcal{G}(R))}{\text{Area}(R)}$$

as the region R shrinks to the point $\mathbf{p}$.

As the following examples show, Theorem 8.1.6 sometimes allows one to find the Gaussian curvature of a surface with no calculation.

Example 8.1.7

For a plane, the unit normal is constant. Thus, for any R, $\mathcal{G}(R)$ is a single point, and thus has zero area. By the theorem, a plane has Gaussian curvature zero everywhere.

For a generalized cylinder, the unit normal is clearly always perpendicular to the rulings of the cylinder, so the image of the Gauss map is contained in the great circle on S^2 formed by intersecting S^2 with the plane passing through its centre perpendicular to the rulings of the cylinder. Any great circle obviously has zero area, so the cylinder has zero Gaussian curvature too.

Finally, for the unit sphere S^2 itself, the unit normal at a point $\mathbf{p}$ is clearly parallel to the radius vector from the centre of the sphere to $\mathbf{p}$. In other words, the Gauss map is the identity map or the antipodal map (depending on the choice of orientation). Both of these maps are obviously equiareal, so the absolute value of the Gaussian curvature of S^2 is 1. In fact, if $\boldsymbol{\sigma}$ is any surface patch of S^2, we have $\mathbf{N} = \pm\boldsymbol{\sigma}$ so with either choice of sign $\mathbf{N}_u \times \mathbf{N}_v = \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v$ is a positive multiple of $\mathbf{N}$ and the Gaussian curvature is $+1$.

EXERCISES

8.1.1 Show that the Gaussian and mean curvatures of the surface $z = f(x, y)$, where f is a smooth function, are

$$K = \frac{f_{xx}f_{yy} - f_{xy}^2}{(1 + f_x^2 + f_y^2)^2}, \quad H = \frac{(1 + f_y^2)f_{xx} - 2f_x f_y f_{xy} + (1 + f_x^2)f_{yy}}{2(1 + f_x^2 + f_y^2)^{3/2}}.$$

8.1.2 Calculate the Gaussian curvature of the helicoid and catenoid (Exercises 4.2.6 and 5.3.1).

8.1.3 Show that the Gaussian and mean curvatures of a surface $\mathcal{S}$ are smooth functions on $\mathcal{S}$.

8.1.4 In the notation of Example 8.1.5, show that if $\boldsymbol{\delta}$ is the principal normal $\mathbf{n}$ of $\boldsymbol{\gamma}$ or its binormal $\mathbf{b}$, then $K = 0$ if and only if $\boldsymbol{\gamma}$ is planar.

8.1.5 What is the effect on the Gaussian and mean curvatures of a surface $\mathcal{S}$ if we apply a dilation of $\mathbb{R}^3$ to $\mathcal{S}$?

8.1.6 Show that the Weingarten map $\mathcal{W}$ of a surface satisfies the quadratic equation

$$\mathcal{W}^2 - 2H\mathcal{W} + K = 0,$$

in the usual notation.

8.1.7 Show that the image of the Gauss map of a generalized cone is a *curve* on S^2, and deduce that the cone has zero Gaussian curvature.

8.1.8 Let $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ be a patch of a surface $\mathcal{S}$. Show that the image under the Gauss map of the part $\boldsymbol{\sigma}(R)$ of $\mathcal{S}$ corresponding to a region $R \subseteq U$ has area

$$\int_R |K| d\mathcal{A}_{\boldsymbol{\sigma}},$$

where K is the Gaussian curvature of $\mathcal{S}$.

5- <N2 <3

8.2.5 Suppose that two surfaces $\mathcal{S}_1$ and $\mathcal{S}_2$ intersect in a curve $\mathcal{C}$ that is a line of curvature of $\mathcal{S}_1$. Show that $\mathcal{C}$ is a line of curvature of $\mathcal{S}_2$ if and only if the angle between the tangent planes of $\mathcal{S}_1$ and $\mathcal{S}_2$ is constant along $\mathcal{C}$.

8.2.6 Let $\mathbf{\Sigma} : W \to \mathbb{R}^3$ be a smooth function defined on an open subset W of $\mathbb{R}^3$ such that, for each fixed value of u (resp. v, w), $\mathbf{\Sigma}(u, v, w)$ is a (regular) surface patch. Assume also that

$$\mathbf{\Sigma}_u \cdot \mathbf{\Sigma}_v = \mathbf{\Sigma}_v \cdot \mathbf{\Sigma}_w = \mathbf{\Sigma}_w \cdot \mathbf{\Sigma}_u = 0. \tag{8.5}$$

This means that the three families of surfaces formed by fixing the values of u, v or w constitute a triply orthogonal system (see Section 5.5).

(i) Show that $\mathbf{\Sigma}_u \cdot \mathbf{\Sigma}_{vw} = \mathbf{\Sigma}_v \cdot \mathbf{\Sigma}_{uw} = \mathbf{\Sigma}_w \cdot \mathbf{\Sigma}_{uv} = 0$.

(ii) Show that, for each of the surfaces in the triply orthogonal system, the matrices $\mathcal{F}_I$ and $\mathcal{F}_{II}$ are diagonal.

(iii) Deduce that the intersection of any surface from one family of the triply orthogonal system with any surface from another family is a line of curvature on both surfaces. (This is called *Dupin's Theorem.*)

8.2.7 Show that, if p, q and r are distinct positive numbers, there are exactly four umbilics on the ellipsoid

$$\frac{x^2}{p^2} + \frac{y^2}{q^2} + \frac{z^2}{r^2} = 1.$$

What happens if p, q and r are not distinct?

8.2.8 Show that the principal curvatures of a surface patch $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ are smooth functions on U provided that $\boldsymbol{\sigma}$ has no umbilics. Show also that the principal curvatures either stay the same or both change sign when $\boldsymbol{\sigma}$ is reparametrized.

8.3 Surfaces of constant Gaussian curvature

We have seen in the examples in Section 8.1 some surfaces of zero and constant positive curvature. For an example of a surface with *constant negative* Gaussian curvature, however, we have to construct a new surface. To this end, we examine again the surface of revolution

$$\boldsymbol{\sigma}(u, v) = (f(u)\cos v, f(u)\sin v, g(u))$$

obtained by rotating the unit-speed curve $u \mapsto (f(u), 0, g(u))$ in the xz-plane around the z-axis. We found in Example 8.1.4 that its Gaussian curvature is

$$K = -\frac{\ddot{f}}{f}. \tag{8.6}$$

Suppose first that $K = 0$ everywhere. Then, Eq. 8.6 gives $\ddot{f} = 0$, so $f(u) = au + b$ for some constants a and b. Since $\dot{f}^2 + \dot{g}^2 = 1$, we get $\dot{g} = \pm\sqrt{1 - a^2}$ (so we must have $|a| \leq 1$) and hence $g(u) = \pm\sqrt{1 - a^2}u + c$, where c is another constant. By applying a translation along the z-axis we can assume that $c = 0$, and by applying a rotation by π about the x-axis, if necessary, we can assume that the sign is $+$. This gives the ruled surface

$$\boldsymbol{\sigma}(u, v) = (b\cos v, b\sin v, 0) + u(a\cos v, a\sin v, \sqrt{1 - a^2}).$$

If $a = 0$ this is a circular cylinder; if $|a| = 1$ it is the xy-plane; and if $0 < |a| < 1$ it is a circular cone (to see this, put $\tilde{u} = au + b$).

Now suppose that $K > 0$, say $K = 1/R^2$, where $R > 0$ is a constant. Then, Eq. 8.6 becomes

$$\ddot{f} + \frac{f}{R^2} = 0,$$

which has the general solution

$$f(u) = a\cos\left(\frac{u}{R} + b\right),$$

where a and b are constants. We can assume that $b = 0$ by performing a reparametrization $\tilde{u} = u + Rb, \tilde{v} = v$. Then, up to a change of sign and adding a constant,

$$g(u) = \int \sqrt{1 - \frac{a^2}{R^2}\sin^2\frac{u}{R}}\, du.$$

The integral in the formula for $g(u)$ can be evaluated in terms of 'elementary' functions only when $a = 0$ or $\pm R$. The case $a = 0$ does not give a surface, and if $a = R$ then $f(u) = R\cos\frac{u}{R}$, $g(u) = R\sin\frac{u}{R}$, and we have a sphere of radius R (the case $a = -R$ can be reduced to this by rotating the surface by π around the z-axis).

Suppose finally that $K < 0$. We can restrict ourselves to the case $K = -1$, as the general case can be obtained from this by applying a dilation of $\mathbb{R}^3$ (see Exercise 8.1.5). In view of the preceding case, we can think of a surface with $K = -1$ as a 'sphere of imaginary radius' $\sqrt{-1}$, or a 'pseudosphere'.

When $K = -1$ the general solution of Eq. 8.6 is

$$f(u) = ae^{u} + be^{-u},$$

where a and b are arbitrary constants. The function $g(u)$ can be expressed in terms of elementary functions only if one of a or b is zero. If $b = 0$ we can assume that $a = 1$ by a reparametrization $u \mapsto u + \text{constant}$, and the case in which $a = 0$ can be reduced to the case $b = 0$ by the reparametrization $u \mapsto -u$. Suppose then that $a = 1$ and $b = 0$; then, $f(u) = e^{u}$ and we can take

$$g(u) = \int \sqrt{1 - e^{2u}}\, du. \tag{8.7}$$

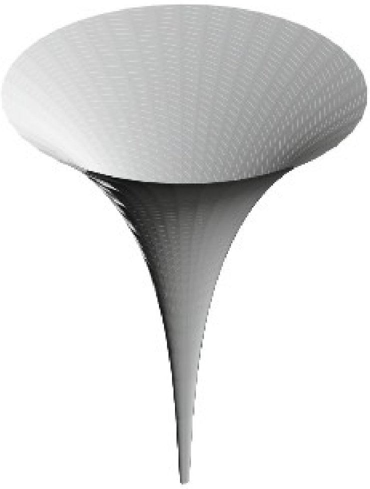
Note that we must have $u \leq 0$ for the integral in Eq. 8.7 to make sense, since otherwise $1 - e^{2u}$ would be negative. The integral can be evaluated by putting $\cos\theta = e^{u}$. Then,

$$\begin{aligned}\int \sqrt{1 - e^{2u}}\, du &= -\int \frac{\sin^2\theta}{\cos\theta}\, d\theta = \sin\theta - \ln(\sec\theta + \tan\theta)\\ &= \sqrt{1 - e^{2u}} - \ln(e^{-u} + \sqrt{e^{-2u} - 1}).\end{aligned}$$

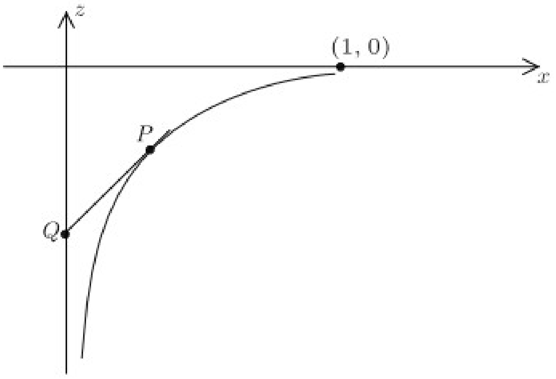
We have omitted the arbitrary constant, but we can take it to be zero by a suitable translation of the surface parallel to the z-axis. Putting $x = f(u)$, $z = g(u)$, and noting that $\cosh^{-1}(v) = \ln(v + \sqrt{v^2 - 1})$, we see that the profile curve in the xz-plane has equation

$$z = \sqrt{1 - x^2} - \cosh^{-1}\left(\frac{1}{x}\right). \tag{8.8}$$

Rotating this curve around the z -axis thus gives a surface which has Gaussian curvature -1 everywhere. Note that, since $u \leq 0$, $x = e^{u}$ is restricted to the range $0 < x \leq 1$.



The curve defined by Eq. 8.8 is called the *tractrix*, and it has an interesting geometrical property. Consider the tangent line at a point P of its graph, and suppose that it intersects the z-axis at the point Q. Let us compute the distance from P to Q.



Suppose that P is the point (x_0, z_0). Either by a direct calculation or by inspecting the calculation of the integral (8.7), one finds that

$$\frac{dz}{dx} = \frac{\sqrt{1-x^2}}{x}.$$

Hence, the tangent line at P has equation

$$z - z_0 = \frac{\sqrt{1-x_0^2}}{x_0}(x - x_0).$$

This meets the z-axis at the point $(0, z_1)$, where

$$z_1 - z_0 = \frac{\sqrt{1-x_0^2}}{x_0}(0 - x_0) = -\sqrt{1-x_0^2}.$$

Hence, the square of the distance from P to Q is

$$x_0^2 + (z_1 - z_0)^2 = x_0^2 + 1 - x_0^2 = 1,$$

so the distance from P to Q is *constant* and equal to 1.

This means that the tractrix has the following description. Let a donkey pull a box of stones by a rope of length 1. Suppose that the donkey is initially at $(0, 0)$, the box is initially at $(1, 0)$, and let the donkey walk slowly along the negative z-axis. Then, the box of stones moves along the tractrix.

8.4 Flat surfaces

In Section 8.3, we gave some examples of surfaces of constant Gaussian curvature K, but this certainly falls well short of a complete classification of such surfaces. It is possible, however, to give a fairly complete description of *flat surfaces*, i.e., surfaces for which $K = 0$ everywhere. To do so, we shall make use of a special parametrization, valid for any surface, described in the following proposition.

Proposition 8.4.1

Let $\mathbf{p}$ be a point of a surface $\mathcal{S}$, and suppose that $\mathbf{p}$ is not an umbilic. Then, there is a surface patch $\boldsymbol{\sigma}(u, v)$ of $\mathcal{S}$ containing $\mathbf{p}$ whose first and second fundamental forms are

$$Edu^2 + Gdv^2 \quad \text{and} \quad Ldu^2 + Ndv^2,$$

respectively, for some smooth functions E,G,L and N.

We recall that a point $\mathbf{p}$ of a surface $\mathcal{S}$ is an umbilic if the two principal curvatures of $\mathcal{S}$ at $\mathbf{p}$ are equal. From Section 8.2, we see that for the patch $\boldsymbol{\sigma}$ in the statement of the proposition, $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ are principal vectors with corresponding principal curvatures L/E and N/G. We call $\boldsymbol{\sigma}$ a *principal patch.*

We assume Proposition 8.4.1 for the moment, and use it to give the proof of

Proposition 8.4.2

Let $\mathbf{p}$ be a point of a flat surface $\mathcal{S}$, and assume that $\mathbf{p}$ is not an umbilic. Then, there is a patch of $\mathcal{S}$ containing $\mathbf{p}$ that is a ruled surface.

Proof

We take a principal patch $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ containing $\mathbf{p}$ as in Proposition 8.4.1, say $\mathbf{p} = \boldsymbol{\sigma}(u_0, v_0)$. By Corollary 8.1.3, the Gaussian curvature $K = LN/EG$. Since the Gaussian curvature is zero everywhere, either $L = 0$ or $N = 0$ at each point of U, and since $\mathbf{p}$ is not an umbilic L and N are not both zero. Suppose that $L(u_0, v_0) \neq 0$, say. Then, $L(u, v) \neq 0$ for (u, v) in some open subset of U containing (u_0, v_0). Hence, by shrinking U if necessary, we can assume that $L \neq 0$ at every point of U. Then, $N = 0$ everywhere, and the second fundamental form of $\boldsymbol{\sigma}$ is Ldu^2.

We shall prove that the parameter curves $u =$ constant are straight lines. Such a curve can be parametrized by $v \mapsto \boldsymbol{\sigma}(u_0, v)$, where u_0 is the constant value of u. A unit tangent vector to this curve is $\mathbf{t} = \boldsymbol{\sigma}_v/G^{1/2}$, so by Proposition 1.1.6 what we have to prove is that $\mathbf{t}_v = \mathbf{0}$.

By the proof of Proposition 8.1.2, the derivatives of the unit normal are

$$\mathbf{N}_u = -E^{-1}L\boldsymbol{\sigma}_u, \quad \mathbf{N}_v = \mathbf{0}. \tag{8.9}$$

Hence, $\mathbf{t}_v \cdot \boldsymbol{\sigma}_u = -EL^{-1}\mathbf{t}_v \cdot \mathbf{N}_u$. Now, $\mathbf{t} \cdot \mathbf{N}_u = 0$ and $\mathbf{N}_{uv} = \mathbf{0}$ by Eq. 8.9, so $\mathbf{t}_v \cdot \mathbf{N}_u = -\mathbf{t} \cdot \mathbf{N}_{uv} = 0$. Hence, $\mathbf{t}_v \cdot \boldsymbol{\sigma}_u = 0$. Next, $\mathbf{t}_v \cdot \mathbf{t} = 0$ since $\mathbf{t}$ is a unit vector by construction, so $\mathbf{t}_v \cdot \boldsymbol{\sigma}_v = 0$. Finally, $\mathbf{t}_v \cdot \mathbf{N} = -\mathbf{t} \cdot \mathbf{N}_v = 0$ by Eq. 8.9 again. Since the vectors $\boldsymbol{\sigma}_u, \boldsymbol{\sigma}_v$ and $\mathbf{N}$ form a basis of $\mathbb{R}^3$, we have proved that $\mathbf{t}_v = \mathbf{0}$. □

Our task, then, is to describe the structure of flat ruled surfaces. We parametrize the ruled surface as in Example 8.1.5:

$$\boldsymbol{\sigma}(u, v) = \boldsymbol{\gamma}(u) + v\boldsymbol{\delta}(u).$$

We found there that $\boldsymbol{\sigma}_u = \dot{\boldsymbol{\gamma}} + v\dot{\boldsymbol{\delta}}$, $\boldsymbol{\sigma}_v = \boldsymbol{\delta}$, the dot denoting d/du, and that the Gaussian curvature of $\boldsymbol{\sigma}$ is zero if and only if

$$\dot{\boldsymbol{\delta}} \cdot (\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v) = 0.$$

Since

$$\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v = \dot{\boldsymbol{\gamma}} \times \boldsymbol{\delta} + v\dot{\boldsymbol{\delta}} \times \boldsymbol{\delta},$$

and $\dot{\boldsymbol{\delta}} \cdot (\dot{\boldsymbol{\delta}} \times \boldsymbol{\delta}) = 0$,

$$K = 0 \quad \text{if and only if} \quad \dot{\boldsymbol{\delta}} \cdot (\dot{\boldsymbol{\gamma}} \times \boldsymbol{\delta}) = 0. \tag{8.10}$$

Thus, $K = 0$ *if and only if* $\dot{\boldsymbol{\gamma}}$, $\boldsymbol{\delta}$ *and* $\dot{\boldsymbol{\delta}}$ *are everywhere linearly dependent.*

To proceed further, let us assume, as we may, that $\boldsymbol{\delta}(u)$ is a unit vector for all values of u. Then, $\boldsymbol{\delta} \cdot \dot{\boldsymbol{\delta}} = 0$. Suppose first that $\dot{\boldsymbol{\delta}}(u) = \mathbf{0}$ for all values of u. Then, $\boldsymbol{\delta}$ is a constant vector and $\boldsymbol{\sigma}$ is a *generalized cylinder.*

Suppose now that $\dot{\boldsymbol{\delta}}$ is never zero. Then, $\boldsymbol{\delta}$ and $\dot{\boldsymbol{\delta}}$ are linearly independent as they are non-zero and perpendicular, so if $\dot{\boldsymbol{\gamma}}, \boldsymbol{\delta}$ and $\dot{\boldsymbol{\delta}}$ are linearly dependent, then

$$\dot{\boldsymbol{\gamma}}(u) = f(u)\boldsymbol{\delta}(u) + g(u)\dot{\boldsymbol{\delta}}(u)$$

for some smooth functions f and g. Assume first that $f = \dot{g}$ everywhere. Then, $\dot{\boldsymbol{\gamma}} = (g\boldsymbol{\delta})^{\cdot}$ and so $\boldsymbol{\gamma} = g\boldsymbol{\delta} + \mathbf{a}$, where $\mathbf{a}$ is a constant vector; hence,

$$\boldsymbol{\sigma}(u, v) = \mathbf{a} + (v + g(u))\boldsymbol{\delta}(u).$$

Putting $\tilde{u} = u$, $\tilde{v} = v + g(u)$, we see that this is a reparametrization of a *generalized cone.*

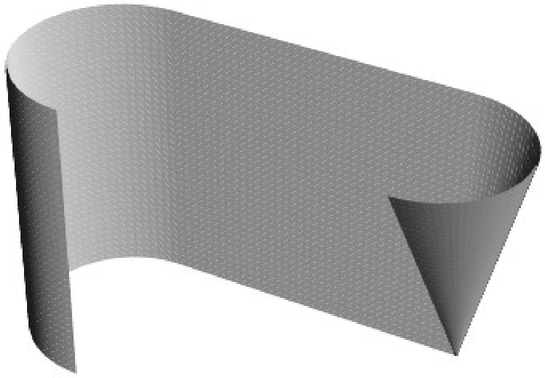
Suppose finally that $\dot{\boldsymbol{\delta}}$ and $f - \dot{g}$ are both nowhere zero. If we define

$$\tilde{\boldsymbol{\gamma}}(u) = \boldsymbol{\gamma}(u) - g(u)\boldsymbol{\delta}(u), \quad \tilde{v} = \frac{v + g(u)}{f(u) - \dot{g}(u)},$$

a short calculation gives

$$\boldsymbol{\sigma}(u,v) = \tilde{\boldsymbol{\gamma}}(u) + \tilde{v}\dot{\tilde{\boldsymbol{\gamma}}}(u),$$

so $\boldsymbol{\sigma}$ is a reparametrization of an open subset of the *tangent developable* of $\tilde{\boldsymbol{\gamma}}$.



Of course, it could be that none of the conditions on $\boldsymbol{\delta}$, f and g considered above are satisfied. In fact, we have only shown that certain open subsets of the surface are parts of generalized cylinders, generalized cones or tangent developables. It is not true that the whole surface must be one of these three types, since flat surfaces of different types can be joined together to make a smooth surface, as shown in the diagram above. It can be shown that the most general flat surface is a patchwork consisting of pieces of generalized cylinders, generalized cones and tangent developables, joined together along segments of straight lines.

The remainder of this section is devoted to the proof of Proposition 8.4.1 and can safely be omitted by readers who are uncomfortable with the use of the inverse function theorem. In fact, we can prove a more general result with no additional effort:

Proposition 8.4.3

Let $\tilde{\boldsymbol{\sigma}} : \tilde{U} \to \mathbb{R}^3$ be a surface patch, and suppose that for all $(\tilde{u},\tilde{v}) \in \tilde{U}$ we are given tangent vectors

$$\boldsymbol{e}_1(\tilde{u},\tilde{v}) = a(\tilde{u},\tilde{v})\tilde{\boldsymbol{\sigma}}_{\tilde{u}} + b(\tilde{u},\tilde{v})\tilde{\boldsymbol{\sigma}}_{\tilde{v}}, \quad \boldsymbol{e}_2(\tilde{u},\tilde{v}) = c(\tilde{u},\tilde{v})\tilde{\boldsymbol{\sigma}}_{\tilde{u}} + d(\tilde{u},\tilde{v})\tilde{\boldsymbol{\sigma}}_{\tilde{v}},$$

whose components a, b, c, d are smooth functions of $(\tilde{u},\tilde{v})$. Assume that, at some point $(\tilde{u}_0,\tilde{v}_0) \in \tilde{U}$, the vectors $\boldsymbol{e}_1(\tilde{u}_0,\tilde{v}_0)$ and $\boldsymbol{e}_2(\tilde{u}_0,\tilde{v}_0)$ are linearly independent. Then, there is an open subset $\tilde{V}$ of $\tilde{U}$ containing $(\tilde{u}_0,\tilde{v}_0)$ and a reparametrization $\boldsymbol{\sigma}(u,v)$ of $\tilde{\boldsymbol{\sigma}}(\tilde{u},\tilde{v})$, for $(\tilde{u},\tilde{v}) \in \tilde{V}$, such that $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ are parallel to $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$, respectively.

Proposition 8.4.1 is a special case of Proposition 8.4.3. In fact, let $\tilde{\boldsymbol{\sigma}}$ be any surface patch of $\mathcal{S}$ containing $\mathbf{p}$, and let $\mathbf{p} = \tilde{\boldsymbol{\sigma}}(\tilde{u}_0, \tilde{v}_0)$. Since the principal curvatures κ_1 and κ_2 of $\tilde{\boldsymbol{\sigma}}$ are distinct at $\mathbf{p}$, and are continuous functions by Exercise 8.2.8, they remain distinct for $(\tilde{u}, \tilde{v})$ in some open set $\tilde{U}$ containing $(\tilde{u}_0, \tilde{v}_0)$ on which $\tilde{\boldsymbol{\sigma}}$ is defined. Let

$$\boldsymbol{e}_1 = \xi_1 \tilde{\boldsymbol{\sigma}}_{\tilde{u}} + \eta_1 \tilde{\boldsymbol{\sigma}}_{\tilde{v}}, \quad \boldsymbol{e}_2 = \xi_2 \tilde{\boldsymbol{\sigma}}_{\tilde{u}} + \eta_2 \tilde{\boldsymbol{\sigma}}_{\tilde{v}}$$

be unit principal vectors corresponding to κ_1 and κ_2; they are perpendicular by Proposition 8.2.1. Let $\boldsymbol{\sigma}(u, v)$ be a reparametrization of $\tilde{\boldsymbol{\sigma}}$ as in Proposition 8.4.3. Then, $\boldsymbol{\sigma}_u \cdot \boldsymbol{\sigma}_v = 0$ because $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ are perpendicular, so the first fundamental form of $\boldsymbol{\sigma}$ is of the form $Edu^2 + Gdv^2$. Also, $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ are principal vectors corresponding to κ_1 and κ_2, so we have

$$(\mathcal{F}_{II} - \kappa_1 \mathcal{F}_I) \begin{pmatrix} 1 \\ 0 \end{pmatrix} = (\mathcal{F}_{II} - \kappa_2 \mathcal{F}_I) \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix},$$

where $\mathcal{F}_I$ and $\mathcal{F}_{II}$ are the matrices associated to the first and second fundamental forms of $\boldsymbol{\sigma}$. Since $\mathcal{F}_I = \begin{pmatrix} E & 0 \\ 0 & G \end{pmatrix}$, these equations imply that $\mathcal{F}_{II} = \begin{pmatrix} \kappa_1 E & 0 \\ 0 & \kappa_2 G \end{pmatrix}$, so the second fundamental form of $\boldsymbol{\sigma}$ is $Ldu^2 + Ndv^2$, where $L = \kappa_1 E$ and $N = \kappa_2 G$.

We are thus left with the proof of Proposition 8.4.3. To begin, we observe that, if

$$\boldsymbol{e} = A \tilde{\boldsymbol{\sigma}}_{\tilde{u}} + B \tilde{\boldsymbol{\sigma}}_{\tilde{v}},$$

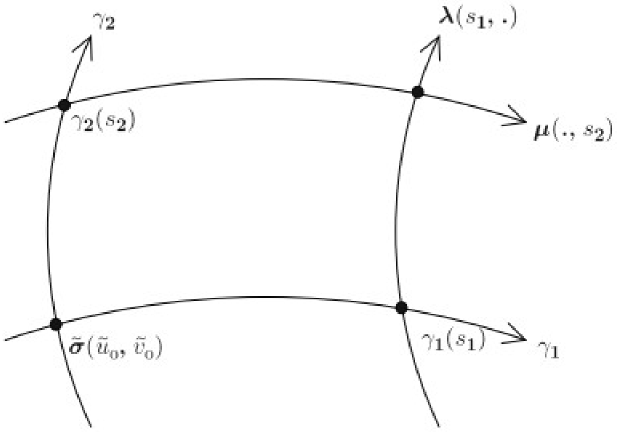
where A and B are any given smooth functions of $(\tilde{u}, \tilde{v}) \in \tilde{U}$, we can find a curve $\boldsymbol{\gamma}$ in $\tilde{\boldsymbol{\sigma}}$ with $\dot{\boldsymbol{\gamma}} = \boldsymbol{e}$ and with any given point $\mathbf{q} = \tilde{\boldsymbol{\sigma}}(\alpha, \beta)$ as starting point $\boldsymbol{\gamma}(0)$. For, finding such a curve $\boldsymbol{\gamma}(t) = \tilde{\boldsymbol{\sigma}}(\tilde{u}(t), \tilde{v}(t))$ is equivalent to solving the pair of ordinary differential equations

$$\dot{\tilde{u}} = A(\tilde{u}, \tilde{v}), \quad \dot{\tilde{v}} = B(\tilde{u}, \tilde{v})$$

with initial conditions $\tilde{u}(0) = \alpha$, $\tilde{v}(0) = \beta$. It is proved in the theory of ordinary differential equations that this problem has a unique solution $\tilde{u}(t), \tilde{v}(t)$ defined on some open interval containing $t = 0$. Moreover, $\tilde{u}$ and $\tilde{v}$ are smooth functions of the three variables t, α and β.

Applying this observation to $\boldsymbol{e} = \boldsymbol{e}_1$, we can find a curve $\boldsymbol{\gamma}_1(s_1)$ in $\tilde{\boldsymbol{\sigma}}$ with $\boldsymbol{\gamma}_1(0) = \tilde{\boldsymbol{\sigma}}(\tilde{u}_0, \tilde{v}_0)$ and $d\boldsymbol{\gamma}_1/ds_1 = \boldsymbol{e}_1$. Now applying the same observation to $\boldsymbol{e} = \boldsymbol{e}_2$, we can find, for each value of s_1 close to 0, a curve $s_2 \mapsto \boldsymbol{\lambda}(s_1, s_2)$ in $\tilde{\boldsymbol{\sigma}}$ with $\partial \boldsymbol{\lambda}/\partial s_2 = \boldsymbol{e}_2$ and $\boldsymbol{\lambda}(s_1, 0) = \boldsymbol{\gamma}_1(s_1)$. Define $(\tilde{u}, \tilde{v})$ as functions of (s_1, s_2) by

$$\tilde{\boldsymbol{\sigma}}(\tilde{u}, \tilde{v}) = \boldsymbol{\lambda}(s_1, s_2). \tag{8.11}$$



γ_2
$\boldsymbol{\lambda}(s_1, .)$
$\gamma_2(s_2)$
$\boldsymbol{\mu}(., s_2)$
$\tilde{\boldsymbol{\sigma}}(\tilde{u}_0, \tilde{v}_0)$
$\gamma_1(s_1)$
γ_1

Differentiating with respect to s_1 and s_2 gives

$$\tilde{\boldsymbol{\sigma}}_{\tilde{u}}\frac{\partial \tilde{u}}{\partial s_1} + \tilde{\boldsymbol{\sigma}}_{\tilde{v}}\frac{\partial \tilde{v}}{\partial s_1} = \boldsymbol{\lambda}_{s_1}, \quad \tilde{\boldsymbol{\sigma}}_{\tilde{u}}\frac{\partial \tilde{u}}{\partial s_2} + \tilde{\boldsymbol{\sigma}}_{\tilde{v}}\frac{\partial \tilde{v}}{\partial s_2} = \boldsymbol{\lambda}_{s_2}.$$

We have

$$\boldsymbol{\lambda}_{s_1}|_{s_2=0} = \frac{d}{ds_1}\boldsymbol{\lambda}(s_1, 0) = \frac{d\boldsymbol{\gamma}_1}{ds_1} = \boldsymbol{e}_1, \quad \boldsymbol{\lambda}_{s_2} = \frac{\partial \lambda}{\partial s_2} = \boldsymbol{e}_2. \tag{8.12}$$

Equating coefficients of $\tilde{\boldsymbol{\sigma}}_{\tilde{u}}$ and $\tilde{\boldsymbol{\sigma}}_{\tilde{v}}$, we see from the last two sets of equations that, at the point $\tilde{\boldsymbol{\sigma}}(\tilde{u}_0, \tilde{v}_0)$, where $s_1 = s_2 = 0$, the Jacobian matrix

$$\begin{pmatrix} \frac{\partial \tilde{u}}{\partial s_1} & \frac{\partial \tilde{u}}{\partial s_2} \\ \frac{\partial \tilde{v}}{\partial s_1} & \frac{\partial \tilde{v}}{\partial s_2} \end{pmatrix} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}. \tag{8.13}$$

Since $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ are linearly independent at $(\tilde{u}_0, \tilde{v}_0)$, this matrix is invertible. By the Inverse Function Theorem 5.6.1, Eq. 8.11 can be solved for (s_1, s_2) as smooth functions of $(\tilde{u}, \tilde{v})$ when $(\tilde{u}, \tilde{v})$ is in some open set $\tilde{W}$ of $\tilde{U}$ containing $(\tilde{u}_0, \tilde{v}_0)$. Thus, $\boldsymbol{\lambda}$ is an allowable surface patch; by Eq. 8.12, it has the property that $\boldsymbol{\lambda}_{s_1} = \boldsymbol{e}_1$ when $s_2 = 0$, and $\boldsymbol{\lambda}_{s_2} = \boldsymbol{e}_2$ everywhere.

We now repeat the procedure, this time starting with a curve $\boldsymbol{\gamma}_2(t_2)$ with $d\boldsymbol{\gamma}_2/dt_2 = \boldsymbol{e}_2$ and $\boldsymbol{\gamma}_2(0) = \tilde{\boldsymbol{\sigma}}(\tilde{u}_0, \tilde{v}_0)$, and then taking a curve $t_1 \mapsto \boldsymbol{\mu}(t_1, t_2)$ with $\partial\boldsymbol{\mu}/\partial t_1 = \boldsymbol{e}_1$ and $\boldsymbol{\mu}(0, t_2) = \boldsymbol{\gamma}_2(t_2)$. This gives an allowable patch $\boldsymbol{\mu}(t_1, t_2)$ such that

$$\boldsymbol{\mu}(t_1, t_2) = \tilde{\boldsymbol{\sigma}}(\tilde{u}, \tilde{v})$$

for $(\tilde{u}, \tilde{v})$ in some open subset $\tilde{Z}$ of $\tilde{U}$ containing $(\tilde{u}_0, \tilde{v}_0)$. This patch has the property that $\boldsymbol{\mu}_{t_1} = \boldsymbol{e}_1$ everywhere and $\boldsymbol{\mu}_{t_2} = \boldsymbol{e}_2$ when $t_1 = 0$.

The parametrization we want is $\boldsymbol{\sigma}(u,v)$, where $\boldsymbol{\sigma}(u,v)$ is the intersection of the curve $s_2 \mapsto \boldsymbol{\lambda}(u,s_2)$ with the curve $t_1 \mapsto \boldsymbol{\mu}(t_1,v)$. Thus, we consider the equations

$$\tilde{\boldsymbol{\sigma}}(\tilde{u},\tilde{v}) = \boldsymbol{\lambda}(u,s_2) = \boldsymbol{\mu}(t_1,v).$$

From Eq. 8.13,

$$\frac{\partial \tilde{u}}{\partial u} = a, \quad \frac{\partial \tilde{v}}{\partial u} = b,$$

and similarly

$$\frac{\partial \tilde{u}}{\partial v} = c, \quad \frac{\partial \tilde{v}}{\partial v} = d.$$

Hence, the Jacobian matrix

$$\begin{pmatrix} \frac{\partial \tilde{u}}{\partial u} & \frac{\partial \tilde{u}}{\partial v} \\ \frac{\partial \tilde{v}}{\partial u} & \frac{\partial \tilde{v}}{\partial v} \end{pmatrix} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}.$$

As usual, the fact that this matrix is invertible means that (u,v) can be expressed as smooth functions of $(\tilde{u},\tilde{v})$, for $(\tilde{u},\tilde{v})$ in some open subset $\tilde{V}$ of $\tilde{W} \cap \tilde{Z}$ containing $(\tilde{u}_0,\tilde{v}_0)$, and we get a reparametrization $\boldsymbol{\sigma}(u,v)$ of $\tilde{\boldsymbol{\sigma}}(\tilde{u},\tilde{v})$. Finally, the equation $\boldsymbol{\sigma}(u,v) = \boldsymbol{\mu}(t_1,v)$ implies that

$$\boldsymbol{\sigma}_u = \frac{\partial t_1}{\partial u}\boldsymbol{\mu}_{t_1} = \frac{\partial t_1}{\partial u}\boldsymbol{e}_1,$$

and similarly

$$\boldsymbol{\sigma}_v = \frac{\partial s_2}{\partial v}\boldsymbol{e}_2,$$

so $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ are parallel to $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ everywhere. □

EXERCISES

8.4.1 Let **p** be a hyperbolic point of a surface $\mathcal{S}$ (see Section 8.2). Show that there is a patch of $\mathcal{S}$ containing **p** whose parameter curves are asymptotic curves (see Exercise 7.3.6). Show that the second fundamental form of such a patch is of the form $2M du dv$.

8.5 Surfaces of constant mean curvature

We now consider surfaces whose mean curvature H is constant. Such surfaces have an interesting physical interpretation: we shall show in Section 12.1 that soap bubbles always adopt the form of a surface of constant mean curvature. In this section we give two simple constructions of surfaces of constant non-zero mean curvature; the case in which $H = 0$ is treated in much more detail in Chapter 12.

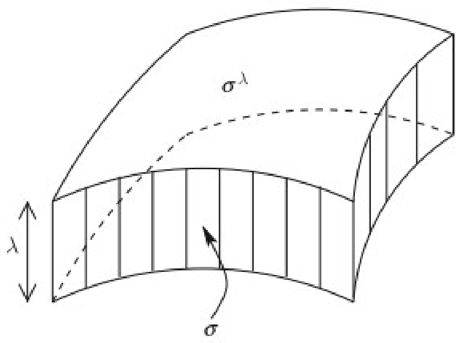
The first of these gives a correspondence between surfaces of constant non-zero mean curvature and surfaces of constant positive Gaussian curvature.

Definition 8.5.1

Let $\mathcal{S}$ be an oriented surface and let $\lambda \in \mathbb{R}$. The *parallel surface* $\mathcal{S}^\lambda$ of $\mathcal{S}$ is

$$\mathcal{S}^\lambda = \{\mathbf{p} + \lambda \mathbf{N}_\mathbf{p} \mid \mathbf{p} \in \mathcal{S}\},$$

where $\mathbf{N}_\mathbf{p}$ is the unit normal of $\mathcal{S}$ at the point $\mathbf{p}$.



Roughly speaking, $\mathcal{S}^\lambda$ is obtained by translating the surface $\mathcal{S}$ at a distance λ perpendicular to itself (but this will not be a genuine translation since $\mathbf{N}_\mathbf{p}$ will in general depend on $\mathbf{p}$).

Proposition 8.5.2

Let κ_1 and κ_2 be the principal curvatures of an oriented surface $\mathcal{S}$, let $\lambda \in \mathbb{R}$ and let $\mathcal{S}^\lambda$ be the corresponding parallel surface of $\mathcal{S}$. Assume that neither κ_1 nor κ_2 is equal to $1/\lambda$ at any point of $\mathcal{S}$. Then,

(i) $\mathcal{S}^\lambda$ is a (smooth) oriented surface, the unit normal of $\mathcal{S}^\lambda$ at $\mathbf{p} + \lambda \mathbf{N}_\mathbf{p}$ being equal to $\epsilon \mathbf{N}_\mathbf{p}$, where ϵ is the sign of $(1 - \lambda\kappa_1)(1 - \lambda\kappa_2)$.

(ii) The principal curvatures of $\mathcal{S}^\lambda$ are $\epsilon\kappa_1/(1 - \lambda\kappa_1)$ and $\epsilon\kappa_2/(1 - \lambda\kappa_2)$, and the corresponding principal vectors are the same as those of $\mathcal{S}$ for the principal curvatures κ_1 and κ_2, respectively.

(iii) The Gaussian and mean curvatures of $\mathcal{S}^\lambda$ are

$$\frac{K}{1 - 2\lambda H + \lambda^2 K} \quad \text{and} \quad \frac{\epsilon(H - \lambda K)}{1 - 2\lambda H + \lambda^2 K},$$

respectively, where K and H are the Gaussian and mean curvatures of $\mathcal{S}$.

Proof

Let $\boldsymbol{\sigma}(u,v)$ be a surface patch of $\mathcal{S}$ with standard unit normal $\mathbf{N}(u,v)$. Define

$$\boldsymbol{\sigma}^{\lambda}(u,v) = \boldsymbol{\sigma}(u,v) + \lambda\mathbf{N}(u,v).$$

By Proposition 8.1.2,

$$\begin{aligned} \boldsymbol{\sigma}_u^{\lambda} &= \boldsymbol{\sigma}_u + \lambda\mathbf{N}_u = (1-\lambda a)\,\boldsymbol{\sigma}_u - \lambda b\,\boldsymbol{\sigma}_v, \\ \boldsymbol{\sigma}_v^{\lambda} &= \boldsymbol{\sigma}_v + \lambda\mathbf{N}_v = -\lambda c\,\boldsymbol{\sigma}_u + (1-\lambda d)\,\boldsymbol{\sigma}_v, \end{aligned} \tag{8.14}$$

where

$$\mathcal{W}_{\boldsymbol{\sigma}} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}$$

is the matrix of the Weingarten map of $\mathcal{S}$ with respect to the basis $\{\boldsymbol{\sigma}_u, \boldsymbol{\sigma}_v\}$ of the tangent plane. Hence,

$$\boldsymbol{\sigma}_u^{\lambda} \times \boldsymbol{\sigma}_v^{\lambda} = (1 - \lambda(a+d) + \lambda^2(ad-bc))\,\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v.$$

Since κ_1 and κ_2 are the eigenvalues of $\mathcal{W}_{\boldsymbol{\sigma}}$ (see Section 8.2), and since the sum and product of the eigenvalues of a matrix are equal to the trace and the determinant of the matrix, respectively,

$$\kappa_1 + \kappa_2 = a + d, \quad \kappa_1\kappa_2 = ad - bc.$$

Hence,

$$\boldsymbol{\sigma}_u^{\lambda} \times \boldsymbol{\sigma}_v^{\lambda} = (1-\lambda\kappa_1)(1-\lambda\kappa_2)\,\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v. \tag{8.15}$$

The assertions in part (i) follow from this equation.

The principal curvatures of $\mathcal{S}^{\lambda}$ are the eigenvalues of the matrix $\mathcal{W}_{\boldsymbol{\sigma}^{\lambda}}$ of the Weingarten map of $\mathcal{S}^{\lambda}$ with respect to the basis $\{\boldsymbol{\sigma}_u^{\lambda}, \boldsymbol{\sigma}_v^{\lambda}\}$. By the proof of Proposition 8.1.2, this is the negative of the matrix expressing $\mathbf{N}_u^{\lambda}$ and $\mathbf{N}_v^{\lambda}$ in terms of $\boldsymbol{\sigma}_u^{\lambda}$ and $\boldsymbol{\sigma}_v^{\lambda}$, where $\mathbf{N}^{\lambda}$ is the standard unit normal of $\boldsymbol{\sigma}^{\lambda}$. Equation 14 says that the matrix expressing $\boldsymbol{\sigma}_u^{\lambda}$ and $\boldsymbol{\sigma}_v^{\lambda}$ in terms of $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ is $I - \lambda\mathcal{W}_{\boldsymbol{\sigma}}$, and the fact that $\mathbf{N}^{\lambda} = \epsilon\mathbf{N}$ implies that $-\epsilon\mathcal{W}_{\boldsymbol{\sigma}}$ is the matrix expressing $\mathbf{N}_u^{\lambda}$ and $\mathbf{N}_v^{\lambda}$ in terms of $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$. Combining these two observations we get

$$\mathcal{W}_{\boldsymbol{\sigma}^{\lambda}} = \epsilon(I - \lambda\mathcal{W}_{\boldsymbol{\sigma}})^{-1}\mathcal{W}_{\boldsymbol{\sigma}}.$$

If T is an eigenvector of $\mathcal{W}_{\boldsymbol{\sigma}}$ with eigenvalue κ, then T is also an eigenvector of $\mathcal{W}_{\boldsymbol{\sigma}^{\lambda}}$ with eigenvalue $\epsilon\kappa/(1-\lambda\kappa)$. The assertions in part (ii) follows from this.

Part (iii) follows from part (ii) by straightforward algebra. □

Corollary 8.5.3

If $\mathcal{S}$ has constant Gaussian curvature $1/R^2$, the parallel surfaces $\mathcal{S}^{\pm R}$ have constant mean curvature $1/2R$. Conversely, if $\mathcal{S}$ has constant mean curvature $1/2R$, the parallel surface $\mathcal{S}^R$ has constant Gaussian curvature $1/R^2$.

Proof

This follows from part (iii) of the proposition by straightforward algebra. For example, if $H = 1/2R$ the Gaussian curvature of $\mathcal{S}^R$ is

$$\frac{K}{1 - 2RH + R^2K} = \frac{K}{R^2K} = \frac{1}{R^2}. \qquad \square$$

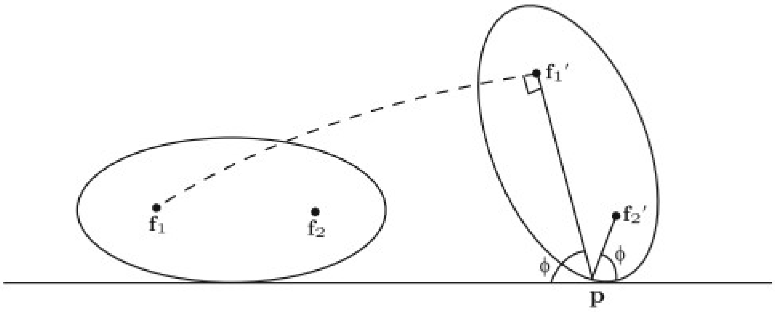
The next construction gives a beautiful geometric description of the surfaces of revolution which have constant non-zero mean curvature in terms of the curve traced out by the focus of an ellipse that rolls without slipping along a straight line (cf. Exercise 2.2.10). Take the ellipse to be

$$\frac{x^2}{p^2} + \frac{(y-q)^2}{q^2} = 1,$$

where $p > q > 0$ are constants. Thus, the ellipse is tangent to the x-axis at the origin. The foci of the ellipse are the points $\mathbf{f}_1 = (-\epsilon p, q)$ and $\mathbf{f}_2 = (\epsilon p, q)$, where the eccentricity $\epsilon = \sqrt{1 - \frac{q^2}{p^2}}$.

Proposition 8.5.4

With the above notation, let $\mathcal{C}$ be the curve traced out by one of the foci of the ellipse as it rolls without slipping along the x-axis. Let $\mathcal{S}$ be the surface obtained by rotating $\mathcal{C}$ around the x-axis. Then, $\mathcal{S}$ has constant non-zero mean curvature.



Proof

We consider a situation in which the ellipse has rolled along the x-axis so that its point of contact with the x-axis is at a point $\mathbf{p}$, the focus $\mathbf{f}_1$ has moved to a point ${\mathbf{f}_1}' = (x, y)$ on $\mathcal{C}$, and the focus $\mathbf{f}_2$ has moved to ${\mathbf{f}_2}' = (X, Y)$, say. Let φ be the angle between $\mathbf{p} - {\mathbf{f}_1}'$ and the x-axis; then φ is also the angle between $\mathbf{p} - {\mathbf{f}_2}'$ and the x-axis by Exercise 1.1.6(iii). Hence,

$$y = \parallel \mathbf{p} - {\mathbf{f}_1}' \parallel \sin\varphi, \quad Y = \parallel \mathbf{p} - {\mathbf{f}_2}' \parallel \sin\varphi$$

and so

$$y + Y = 2p\sin\varphi$$

by Exercise 1.1.6(i). But Exercise 1.1.6(ii) gives $yY = q^2$ so

$$y + \frac{q^2}{y} = 2p\sin\varphi. \tag{8.16}$$

Now, since the ellipse rolls without slipping, the point of contact of the ellipse with the x-axis is stationary. This implies that the point ${\mathbf{f}_1}'$ moves as if rotating instantaneously about $\mathbf{p}$, so that the tangent vector to $\mathcal{C}$ at ${\mathbf{f}_1}'$ is perpendicular to $\mathbf{p} - {\mathbf{f}_1}'$. (If this heuristic argument is unconvincing, an analytical proof can be found in Exercise 2.2.10.) It follows that

$$\frac{dy}{dx} = \cot\varphi. \tag{8.17}$$

Eliminating φ between Eqs. 8.16 and 8.17 gives

$$y^2 + q^2 = \frac{2py}{\sqrt{1 + \left(\frac{dy}{dx}\right)^2}}. \tag{8.18}$$

The surface $\mathcal{S}$ obtained by rotating $\mathcal{C}$ around the x-axis can be parametrized by

$$\boldsymbol{\sigma}(x, \theta) = (x, y\cos\theta, y\sin\theta)$$

where θ is the angle of rotation. The first and second fundamental forms of $\boldsymbol{\sigma}$ are

$$\left(1 + \left(\frac{dy}{dx}\right)^2\right) dx^2 + y^2 d\theta^2 \quad \text{and} \quad -\frac{d^2y}{dx^2}dx^2 + \frac{y}{\sqrt{1 + \left(\frac{dy}{dx}\right)^2}}d\theta^2,$$

respectively. Using the formula in Corollary 8.1.3, the mean curvature is found to be

$$H = \frac{1}{2y\sqrt{1 + \left(\frac{dy}{dx}\right)^2}} - \frac{\frac{d^2y}{dx^2}}{2\left(1 + \left(\frac{dy}{dx}\right)^2\right)^{3/2}}. \tag{8.19}$$

Differentiating both sides of Eq. 8.18 we get

$$2y\frac{dy}{dx} = \frac{2p\frac{dy}{dx}}{\sqrt{1+\left(\frac{dy}{dx}\right)^2}} - \frac{2py\frac{dy}{dx}\frac{d^2y}{dx^2}}{\left(1+\left(\frac{dy}{dx}\right)^2\right)^{3/2}}.$$

Dividing both sides by $4py\frac{dy}{dx}$ and comparing with Eq. 8.19 shows that the surface $\mathcal{S}$ has mean curvature $1/2p$. ☐

EXERCISES

8.5.1 Suppose that the first fundamental form of a surface patch $\boldsymbol{\sigma}(u,v)$ is of the form $E(du^2+dv^2)$. Prove that $\boldsymbol{\sigma}_{uu}+\boldsymbol{\sigma}_{vv}$ is perpendicular to $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$. Deduce that the mean curvature $H=0$ everywhere if and only if the Laplacian

$$\boldsymbol{\sigma}_{uu}+\boldsymbol{\sigma}_{vv}=\mathbf{0}.$$

Show that the surface patch

$$\boldsymbol{\sigma}(u,v)=\left(u-\frac{u^3}{3}+uv^2, v-\frac{v^3}{3}+u^2v, u^2-v^2\right)$$

has $H=0$ everywhere. (A picture of this surface can be found in Section 12.2.)

8.5.2 Prove that $H=0$ for the surface

$$z=\ln\left(\frac{\cos y}{\cos x}\right).$$

(A picture of this surface can also be found in Section 12.2.)

8.5.3 Let $\boldsymbol{\sigma}(u,v)$ be a surface with first and second fundamental forms Edu^2+Gdv^2 and Ldu^2+Ndv^2, respectively (cf. Proposition 8.4.1). Define

$$\boldsymbol{\Sigma}(u,v,w)=\boldsymbol{\sigma}(u,v)+w\mathbf{N}(u,v),$$

where $\mathbf{N}$ is the standard unit normal of $\boldsymbol{\sigma}$. Show that the three families of surfaces obtained by fixing the values of u, v or w in $\boldsymbol{\Sigma}$ form a triply orthogonal system (see Section 5.5). The surfaces $w=$ constant are parallel surfaces of $\boldsymbol{\sigma}$. Show that the surfaces $u=$ constant and $v=$ constant are flat ruled surfaces.

5- 672 N 3

10

Gauss' Theorema Egregium

One of Gauss' most important discoveries about surfaces is that the Gaussian curvature is unchanged when the surface is bent without stretching. Gauss called this result 'egregium', and the Latin word for 'remarkable' has remained attached to his theorem ever since. We shall deduce the Theorema Egregium from two results which relate the first and second fundamental forms of a surface, and which have other important consequences.

10.1 The Gauss and Codazzi–Mainardi equations

It is natural to ask if there are any relations between the first and second fundamental forms of a surface. Note that, by Examples 6.1.2, 6.1.4, 7.1.1 and 7.1.2, the plane and the unit cylinder, when suitably parametrized, have the same first fundamental form but different second fundamental forms, and so the second fundamental form certainly cannot be 'deduced' from the first. Nevertheless, there are some nontrivial relations between the two forms.

Proposition 10.1.1 (Codazzi–Mainardi Equations)

Let

$$Edu^2 + 2Fdudv + Gdv^2 \quad \text{and} \quad Ldu^2 + 2Mdudv + Ndv^2$$

5- /N2 N<3

(ii) Show that $u^2(\tilde{E}-1) = v^2(\tilde{G}-1)$, and by considering the Taylor expansions of $\tilde{E}$ and $\tilde{G}$ about $u = v = 0$, deduce that

$$G(r, \theta) = r^2 + kr^4 + \text{remainder}$$

for some constant k, where remainder$/r^4$ tends to zero as r tends to zero.

(iii) Show that $k = -K(P)/3$, where $K(P)$ is the value of the Gaussian curvature of $\mathcal{S}$ at P.

10.2.3 With the notation of Exercises 9.5.1 and 10.2.2, show that:

(i) The circumference of the geodesic circle with centre P and radius R is

$$C_R = 2\pi R\left(1 - \frac{K(P)}{6}R^2 + \text{remainder}\right),$$

where remainder$/R^2$ tends to zero as R tends to zero.

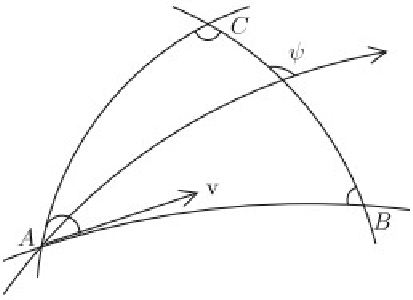
(ii) The area inside the geodesic circle in (i) is

$$A_R = \pi R^2\left(1 - \frac{K(P)}{12}R^2 + \text{remainder}\right),$$

where the remainder satisfies the same condition as in (i).

Verify that these formulas are consistent with those in spherical geometry obtained in Exercise 6.5.3.

10.2.4 Let A, B and C be the vertices of a triangle $\mathcal{T}$ on a surface $\mathcal{S}$ whose sides are arcs of geodesics, and let α, β and γ be its internal angles (so that α is the angle at A, etc.). Assume that the triangle is contained in a geodesic patch $\boldsymbol{\sigma}$ as in Exercise 9.5.1 with $P = A$. Thus, with the notation in that exercise, if we take $\mathbf{v}$ to be tangent at A to the side passing through A and B, then the sides meeting at A are the parameter curves $\theta = 0$ and $\theta = \alpha$, and the remaining side can be parametrized by $\boldsymbol{\gamma}(\theta) = \boldsymbol{\sigma}(f(\theta), \theta)$ for some smooth function f and $0 \leq \theta \leq \alpha$.



(i) Use the geodesic equations (9.2) to show that

$$f'' - \frac{f'\lambda'}{\lambda^2} = \frac{1}{2}\frac{\partial G}{\partial r},$$

where a dash denotes $d/d\theta$ and $\lambda = \parallel \boldsymbol{\gamma}' \parallel$.

(ii) Show that, if $\psi(\theta)$ is the angle between $\boldsymbol{\sigma}_r$ and the tangent vector to the side opposite A at $\boldsymbol{\gamma}(\theta)$, then

$$\psi'(\theta) = -\frac{\partial\sqrt{G}}{\partial r}(f(\theta), \theta).$$

(iii) Show that, if K is the Gaussian curvature of $\mathcal{S}$,

$$\int_{\mathcal{T}} K \, d\mathcal{A}_{\boldsymbol{\sigma}} = \alpha + \beta + \gamma - \pi.$$

This result will be generalized in Corollary 13.2.3.

10.2.5 Show that the Gaussian curvature of the Möbius band in Example 4.5.3 is equal to $-1/4$ everywhere along its median circle. Deduce that this Möbius band *cannot* be constructed by taking a strip of paper and joining the ends together with a half-twist. (The analytic description of the 'cut and paste' Möbius band is more complicated than the version in Example 4.5.3.)

10.2.6 Show that the only isometries from the catenoid to itself are products of rotations around its axis, reflections in planes containing the axis, and reflection in the plane containing the waist of the catenoid.

10.3 Surfaces of constant Gaussian curvature

The results of the preceding two sections enable us to gain a good understanding of surfaces of constant Gaussian curvature. We begin with the following local description.

Theorem 10.3.1

Any point of a surface of constant Gaussian curvature is contained in a patch that is isometric to an open subset of a plane, a sphere or a pseudosphere.

5- 7 2 T 3

11.1 Upper half-plane model

We saw in Example 9.3.3 that if the pseudosphere is parametrized as

$$\tilde{\boldsymbol{\sigma}}(v, w) = \left(\frac{1}{w} \cos v, \frac{1}{w} \sin v, \sqrt{1 - \frac{1}{w^2}} - \cosh^{-1} w \right),$$

where we must have $w > 1$ for $\tilde{\boldsymbol{\sigma}}$ to be well defined and smooth, its geodesics correspond to arcs of circles and straight lines in the vw-plane that intersect the v-axis perpendicularly. The line $w = 1$ appears to be a rather artificial boundary in the vw-plane, since the geodesics are well defined in the entire region $w > 0$. On the other hand, the line $w = 0$ is a 'real' boundary since the first fundamental form

$$\frac{dv^2 + dw^2}{w^2} \tag{11.1}$$

of the pseudosphere is undefined when $w = 0$. It is therefore natural to ask if there is a surface that corresponds to the whole of the half-plane $w > 0$ with this first fundamental form. In fact, there is no such surface for a celebrated theorem of Hilbert shows that there is no surface with constant negative Gaussian curvature that is 'geodesically complete', i.e., a surface for which all geodesics can be extended indefinitely in both directions (see Exercise 10.1.3).

One possible response to Hilbert's theorem is essentially to ignore it: all those properties of surfaces that depend only on the first fundamental form (lengths, angles, areas, geodesics, local isometries, ...) can still be studied for the half-plane

$$\mathcal{H} = \{(v, w) \in \mathbb{R}^2 \mid w > 0\}$$

equipped with the first fundamental form (11.1). They will then be called hyperbolic lengths, hyperbolic angles, etc. (We shall see the reason for the adjective 'hyperbolic' later.)

It will often be convenient to identify $\mathbb{R}^2$ with the set of complex numbers $\mathbb{C}$ via $(v, w) \leftrightarrow v + iw$, so that

$$\mathcal{H} = \{z \in \mathbb{C} \mid \mathfrak{Im}(z) > 0\}$$

is the set of complex numbers with positive imaginary part.

The first thing to observe is that $\mathcal{H}$ is a 'conformal model':

Proposition 11.1.1

Hyperbolic angles in $\mathcal{H}$ are the same as Euclidean angles.

Proof

This is just because the first fundamental form (11.1) of $\mathcal{H}$ is a multiple of $dv^2 + dw^2$ (see Corollary 6.3.4). $\square$

The 'hyperbolic lines' are the geodesics in $\mathcal{H}$, which were determined in Example 9.3.3.

Proposition 11.1.2

The geodesics in $\mathcal{H}$ are the half-lines parallel to the imaginary axis and the semicircles with centres on the real axis.

Here are some simple properties of hyperbolic lines.

Proposition 11.1.3

(i) There is a unique hyperbolic line passing through any two distinct points of $\mathcal{H}$.

(ii) The parallel axiom does not hold in $\mathcal{H}$.

In the following proof, and later in this chapter, 'lines' and 'circles' will mean Euclidean lines and circles ('hyperbolic line' means 'geodesic'). On the other hand, 'lengths' and 'angles' will always mean hyperbolic lengths and angles, unless explicitly stated otherwise.

Proof

(i) Let $a, b \in \mathcal{H}$, $a \neq b$. If the line passing through a and b is parallel to the imaginary axis, the unique hyperbolic line passing through the points a and b is the half-line containing them. If the line through a and b is not parallel to the imaginary axis, its perpendicular bisector intersects the real axis at some point c, say, and the unique hyperbolic line passing through a and b is the semicircle with centre c and radius $|a - c| = |b - c|$.
(ii) Take l to be the imaginary axis and let $a \in \mathcal{H}$ be any point not on l. For definiteness, assume that the real part $\mathfrak{Re}(a) > 0$. Then, the perpendicular bisector of the line joining a to the origin intersects the real axis at some point $b > 0$. Let c be a real number greater than b; then the semicircle with centre c passing through a is a hyperbolic line in $\mathcal{H}$ that does not intersect l. Of course,

the half-line through a parallel to the imaginary axis is another hyperbolic line with the same property (it can be regarded as the limiting case when $c \to \infty$). □

Since there is a unique hyperbolic line passing through any two points $a, b \in \mathcal{H}$, it makes sense to define the *hyperbolic distance* $d_{\mathcal{H}}(a, b)$ between a and b to be the length of the hyperbolic line segment joining them. It is shown in Exercise 11.2.1 that this is actually the hyperbolic length of the shortest curve joining a and b.

Proposition 11.1.4

The hyperbolic distance between two points $a, b \in \mathcal{H}$ is

$$d_{\mathcal{H}}(a, b) = 2 \tanh^{-1} \frac{|b - a|}{|b - \bar{a}|}.$$

In this formula, $\bar{a}$ denotes the complex conjugate of the complex number a. The appearance of the hyperbolic tangent gives an indication of the reason why the geometry of $\mathcal{H}$ is called 'hyperbolic geometry'.

Proof

There are two cases, depending on whether the hyperbolic line joining a and b is a semicircle or a half-line. We shall deal with the semicircle case, leaving the simpler case of the half-line to Exercise 11.1.2.

Suppose then that a and b lie on the semicircle with centre c on the real axis and radius r. The semicircle can be parametrized by

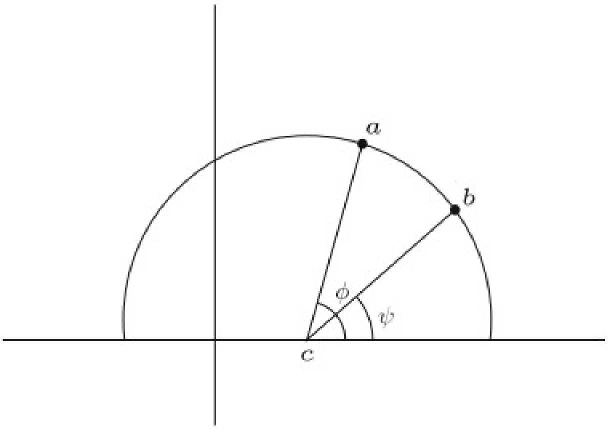
$$v = c + r\cos\theta, \quad w = r\sin\theta.$$

Writing d for $d_{\mathcal{H}}(a, b)$ and denoting $d/d\theta$ by a dot, we have

$$d = \int_{\varphi}^{\psi} \sqrt{\frac{\dot{v}^2 + \dot{w}^2}{w^2}}\, d\theta = \int_{\varphi}^{\psi} \sqrt{\frac{r^2 \sin^2\theta + r^2\cos^2\theta}{r^2\sin^2\theta}}\, d\theta = \int_{\varphi}^{\psi} \frac{d\theta}{\sin\theta},$$

where $\varphi = \arg(a - c)$, $\psi = \arg(b - c)$ (note that d is independent of the radius of the semicircle). Hence,

$$d = \ln \frac{\tan\frac{\psi}{2}}{\tan\frac{\varphi}{2}}.$$



Now,

$$\tanh\frac{d}{2} = \frac{e^d - 1}{e^d + 1} = \frac{\tan\frac{\psi}{2} - \tan\frac{\varphi}{2}}{\tan\frac{\psi}{2} + \tan\frac{\varphi}{2}} = \frac{\sin\frac{\psi}{2}\cos\frac{\varphi}{2} - \cos\frac{\psi}{2}\sin\frac{\varphi}{2}}{\sin\frac{\psi}{2}\cos\frac{\varphi}{2} + \cos\frac{\psi}{2}\sin\varphi 2} = \frac{\sin\frac{\psi-\varphi}{2}}{\sin\frac{\psi+\varphi}{2}}. \tag{11.2}$$

On the other hand,

$$\begin{aligned} |b-a|^2 &= r^2((\cos\psi - \cos\varphi)^2 + (\sin\psi - \sin\varphi)^2) \\ &= 2r^2(1 - \cos(\psi - \varphi)) = 4r^2\sin^2\frac{\psi - \varphi}{2}, \end{aligned}$$

and similarly

$$|b - \bar{a}|^2 = 4r^2\sin^2\frac{\psi + \varphi}{2}.$$

Combining the last two equations with Eq. 11.2 gives

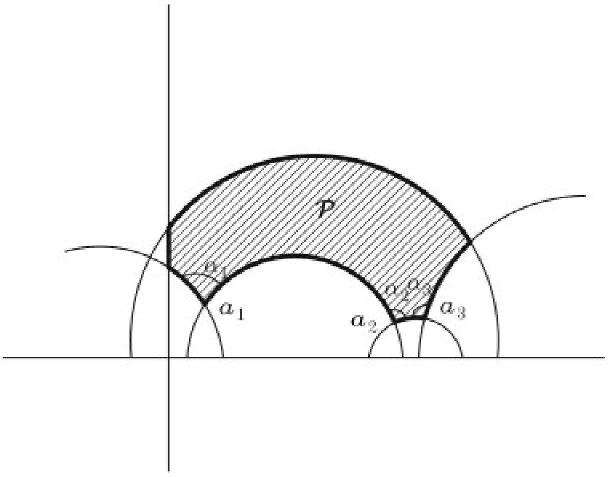
$$\tanh\frac{d}{2} = \frac{|b-a|}{|b-\bar{a}|}. \qquad \square$$

We conclude this section with another beautiful formula, this time for the area of a hyperbolic polygon, i.e., a polygon whose sides are hyperbolic lines.

Theorem 11.1.5

Let $\mathcal{P}$ be a n-sided hyperbolic polygon in $\mathcal{H}$ with internal angles $\alpha_1, \alpha_2, \ldots, \alpha_n$. Then, the hyperbolic area of the polygon is given by

$$\mathcal{A}(\mathcal{P}) = (n-2)\pi - \alpha_1 - \alpha_2 - \cdots - \alpha_n.$$



In particular, for a triangle with angles α, β, γ, the area is

$$\pi - \alpha - \beta - \gamma.$$

This should be compared with the well-known formula

$$\alpha + \beta + \gamma = \pi$$

for the sum of the angles of a Euclidean triangle with straight line sides, and the formula

$$\alpha + \beta + \gamma - \pi$$

for the area of a triangle on the unit sphere with geodesic (i.e., great circle) sides (Theorem 6.4.7).

Proof 11.1.5 Let $a_1, \ldots, a_n$ be the vertices of $\mathcal{P}$ and $\mathcal{C}$ its boundary, consisting of n hyperbolic line segments $a_1a_2, a_2a_3, \ldots, a_na_1$ (we assume that α_1 is the internal angle of $\mathcal{P}$ at the vertex a_1, etc.). Since the first fundamental form is $(dv^2 + dw^2)/w^2$, the area of $\mathcal{P}$ is

$$\int_{\mathcal{P}} \frac{dvdw}{w^2}.$$

We evaluate this integral by using Green's theorem (Section 3.2):

$$\int_{\mathcal{C}} pdv + qdw = \int_{\mathcal{P}} \left(\frac{\partial q}{\partial v} - \frac{\partial p}{\partial w} \right) dvdw,$$

where p and q are smooth functions of (v, w). Taking $p = 1/w$ and $q = 0$ gives

$$\int_{\mathcal{P}} \frac{dv dw}{w^2} = \int_{\mathcal{C}} \frac{dv}{w}. \tag{11.3}$$

To evaluate this integral we first prove the following lemma.

Lemma 11.1.6

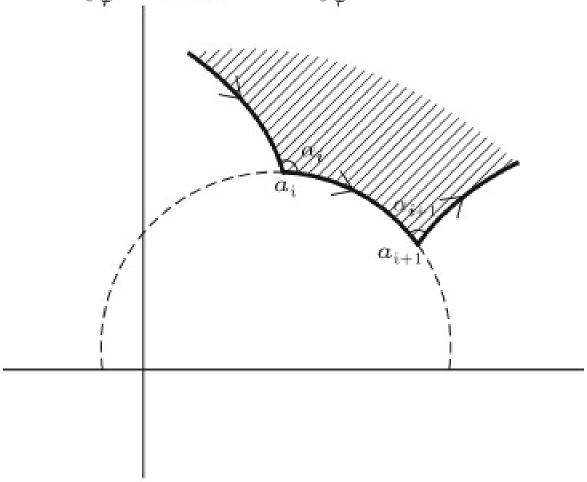
Let a and b be the endpoints of a segment l of a hyperbolic line in $\mathcal{H}$ that forms part of a semicircle with centre p on the real axis, and suppose that the radius vectors joining p to a and p to b make angles φ and ψ, respectively, with the positive real axis (see the diagram in the proof of Proposition 11.1.4). Then,

$$\int_l \frac{dv}{w} = \varphi - \psi.$$

Note that the integral is independent of the radius of the semicircle, and that the formula is correct even if the hyperbolic line is part of a half-line, for in that case the integral vanishes since v is constant along the hyperbolic line.

Proof 11.1.6 We parametrize the hyperbolic line by $v = r\cos\theta$, $w = r\sin\theta$, where r is the radius of the semicircle. Then, the integral is

$$\int_{\varphi}^{\psi} \frac{-r\sin\theta\, d\theta}{r\sin\theta} = -\int_{\varphi}^{\psi} d\theta = \varphi - \psi. \qquad \square$$



Returning to the proof of Theorem 11.1.5, let φ_i and ψ_i be the angles defined in the lemma corresponding to the side with endpoints a_i and a_{i+1}, for $i = 1, \ldots, n$ (it is understood that a_{n+1} means a_1). By Eq. 11.3 and the lemma,

$$\int_{\mathcal{P}} \frac{dvdw}{w^2} = \sum_{i=1}^{n} (\varphi_i - \psi_i). \tag{11.4}$$

We can simplify this sum by considering the change in direction of the outward-pointing normal of $\mathcal{P}$ as we traverse its boundary in an anticlockwise direction. As we traverse the side with endpoints a_i and a_{i+1}, the outward normal rotates anticlockwise through an angle $\psi_i - \varphi_i$, while at the vertex a_i it rotates by $\pi - \alpha_i$. Hence, as we traverse the boundary of $\mathcal{P}$, the outward normal rotates through an angle

$$n\pi + \sum_{i=1}^{n} (\psi_i - \varphi_i - \alpha_i).$$

But this angle of rotation is 2π (cf. Theorem 3.1.4), so we have the equation

$$2\pi = n\pi + \sum_{i=1}^{n} (\psi_i - \varphi_i - \alpha_i).$$

Rearranging, we get

$$\sum_{i=1}^{n} (\varphi_i - \psi_i) = (n-2)\pi - \sum_{i=1}^{n} \alpha_i.$$

By Eq. 11.4, this is the desired area. □

Note that the area of a hyperbolic triangle, i.e., a triangle whose sides are hyperbolic lines, depends only on its angles. We found in Proposition 6.5.8 that the same result holds in spherical geometry, but as we noted there this is completely different to the Euclidean situation, where we can change the size of a triangle (and hence its area) without changing its angles. In fact, we shall show in the next section that, as in spherical geometry (Exercise 6.5.2), two hyperbolic triangles with the same angles are *congruent*. But first we must discuss what congruence means in hyperbolic geometry.

EXERCISES

11.1.1 Show that, if l is a half-line geodesic in $\mathcal{H}$ and a is a point not on l, there are infinitely many hyperbolic lines passing through a that do not intersect l.

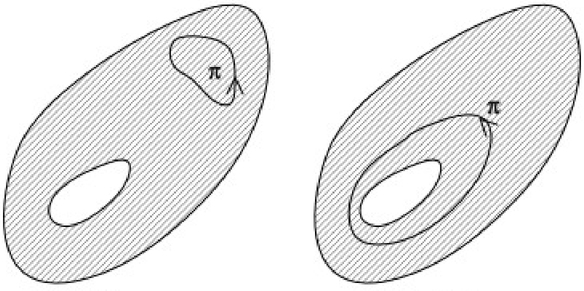
The Gauss–Bonnet theorem

The Gauss–Bonnet theorem is the most beautiful and profound result in the theory of surfaces. Its most important version relates the average of the Gaussian curvature to a property of the surface called its 'Euler number' which is 'topological', i.e., it is unchanged by any diffeomorphism of the surface. Such diffeomorphisms will in general change the value of the Gaussian curvature, but the theorem says that its average over the surface does *not* change. The real importance of the Gauss–Bonnet theorem is as a prototype of analogous results which apply in higher dimensional situations, and which relate *geometrical* properties to *topological* ones. The study of such relations was one of the most important themes of twentieth century mathematics, and continues to be actively studied today.

13.1 Gauss–Bonnet for simple closed curves

The simplest version of the Gauss–Bonnet Theorem involves *simple closed curves* on a surface. In the special case when the surface is a plane, these curves have been discussed in Section 3.1. For a general surface, we make the following definition.

Andrew Pressley, *Elementary Differential Geometry: Second Edition*,
Springer Undergraduate Mathematics Series, DOI 10.1007/978-1-84882-891-9_13,
© Springer-Verlag London Limited 2010



Definition 13.1.1

A curve $\boldsymbol{\gamma}(t) = \boldsymbol{\sigma}(u(t), v(t))$ on a surface patch $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ is called a *simple closed curve* with *period* T if $\boldsymbol{\pi}(t) = (u(t), v(t))$ is a simple closed curve in $\mathbb{R}^2$ with period T such that the region $\text{int}(\boldsymbol{\pi})$ of $\mathbb{R}^2$ enclosed by $\boldsymbol{\pi}$ is entirely contained in U (see the diagrams above). The curve $\boldsymbol{\gamma}$ is said to be *positively-oriented* if $\boldsymbol{\pi}$ is positively-oriented. Finally, the image of $\text{int}(\boldsymbol{\pi})$ under the map $\boldsymbol{\sigma}$ is defined to be the *interior* $\text{int}(\boldsymbol{\gamma})$ of $\boldsymbol{\gamma}$.

We can now state the first version of the Gauss–Bonnet Theorem.

Theorem 13.1.2

Let $\boldsymbol{\gamma}(s)$ be a unit-speed simple closed curve on a surface patch $\boldsymbol{\sigma}$ of length $\ell(\boldsymbol{\gamma})$, and assume that $\boldsymbol{\gamma}$ is positively-oriented. Then,

$$\int_0^{\ell(\boldsymbol{\gamma})} \kappa_g ds = 2\pi - \int_{\text{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}},$$

where κ_g is the geodesic curvature of $\boldsymbol{\gamma}$, K is the Gaussian curvature of $\boldsymbol{\sigma}$ and $d\mathcal{A}_{\boldsymbol{\sigma}}$ is the area element of $\boldsymbol{\sigma}$ (see Section 6.4).

We use s to denote the parameter of $\boldsymbol{\gamma}$ to emphasize that $\boldsymbol{\gamma}$ is unit-speed. The double integral on the right-hand side of the equation in Theorem 13.1.2 is called the *total curvature* of the region $\text{int}(\boldsymbol{\gamma})$.

Proof

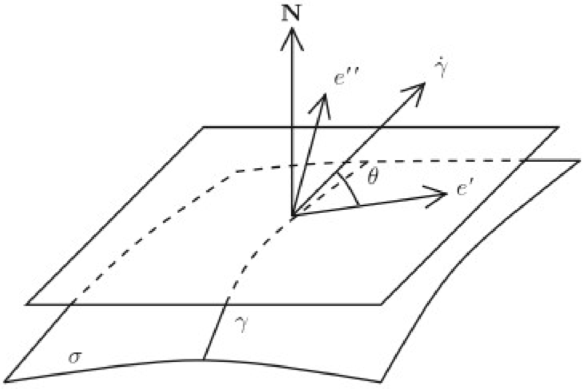
We start by computing the geodesic curvature of $\boldsymbol{\gamma}$. For this, we shall make use of a smooth *orthonormal* basis $\{\boldsymbol{e}', \boldsymbol{e}''\}$ of the tangent plane at each point of the surface patch, where 'smooth' means that $\boldsymbol{e}'$ and $\boldsymbol{e}''$ are smooth functions of the surface parameters (u, v). Then, $\{\boldsymbol{e}', \boldsymbol{e}'', \mathbf{N}\}$ is an orthonormal basis of $\mathbb{R}^3$ ($\mathbf{N}$ being the standard unit normal of $\boldsymbol{\sigma}$), and we shall assume that it is *right-handed*, i.e., that $\mathbf{N} = \boldsymbol{e}' \times \boldsymbol{e}''$. This can always be achieved by interchanging $\boldsymbol{e}'$ and $\boldsymbol{e}''$ if necessary. Note that the dashes on $\boldsymbol{e}'$ and $\boldsymbol{e}''$ have nothing to do with derivatives.

Let $\theta(s)$ be the oriented angle $\widehat{\boldsymbol{e}'\dot{\boldsymbol{\gamma}}}$ between the unit tangent vector $\dot{\boldsymbol{\gamma}}(s)$ of $\boldsymbol{\gamma}$ at $\boldsymbol{\gamma}(s)$ and the unit vector $\boldsymbol{e}'$ at the same point. Thus,

$$\dot{\boldsymbol{\gamma}} = \cos\theta \boldsymbol{e}' + \sin\theta \boldsymbol{e}''. \tag{13.1}$$

Then,

$$\mathbf{N} \times \dot{\boldsymbol{\gamma}} = -\sin\theta \boldsymbol{e}' + \cos\theta \boldsymbol{e}''. \tag{13.2}$$



Now, by Eq. 13.1,

$$\ddot{\boldsymbol{\gamma}} = \cos\theta \dot{\mathbf{e}}' + \sin\theta \dot{\mathbf{e}}'' + \dot{\theta}(-\sin\theta \boldsymbol{e}' + \cos\theta \boldsymbol{e}''), \tag{13.3}$$

so by Eqs. 13.2 and 13.3 the geodesic curvature of $\boldsymbol{\gamma}$ is

$$\begin{aligned}
\kappa_g &= (\mathbf{N} \times \dot{\boldsymbol{\gamma}}) \cdot \ddot{\boldsymbol{\gamma}} \quad \text{(see Section 7.3)} \\
&= \dot{\theta}(-\sin\theta \boldsymbol{e}' + \cos\theta \boldsymbol{e}'') \cdot (-\sin\theta \boldsymbol{e}' + \cos\theta \boldsymbol{e}'') \\
&\qquad +(-\sin\theta \boldsymbol{e}' + \cos\theta \boldsymbol{e}'') \cdot (\cos\theta \dot{\mathbf{e}}' + \sin\theta \dot{\mathbf{e}}'') \\
&= \dot{\theta} + \cos^2\theta(\dot{\mathbf{e}}' \cdot \boldsymbol{e}'') - \sin^2\theta(\dot{\mathbf{e}}'' \cdot \boldsymbol{e}') \\
&\qquad + \sin\theta\cos\theta(\dot{\mathbf{e}}'' \cdot \boldsymbol{e}'' - \dot{\mathbf{e}}' \cdot \boldsymbol{e}') \quad \text{(by Eqs. 13.1 and 13.2).}
\end{aligned}$$

Since $\boldsymbol{e}'$ and $\boldsymbol{e}''$ are perpendicular unit vectors,

$$\boldsymbol{e}' \cdot \dot{\mathbf{e}}' = \boldsymbol{e}'' \cdot \dot{\mathbf{e}}'' = 0, \quad \dot{\mathbf{e}}' \cdot \boldsymbol{e}'' = -\boldsymbol{e}' \cdot \dot{\mathbf{e}}''.$$

Hence,

$$\kappa_g = \dot{\theta} - \boldsymbol{e}' \cdot \dot{\mathbf{e}}''. \tag{13.4}$$

Thus, to compute the left-hand side of the equation in Theorem 13.1.2, we must compute the integrals of $\dot{\theta}$ and of $\boldsymbol{e}' \cdot \dot{\boldsymbol{e}}''$ around the curve $\boldsymbol{\gamma}$. We begin with the latter, for which we shall need the following lemma.

Lemma 13.1.3

Let

$$Edu^2 + 2Fdudv + Gdv^2 \quad \text{and} \quad Ldu^2 + 2Mdudv + Ndv^2$$

be the first and second fundamental forms of $\boldsymbol{\sigma}$, respectively. Then, with the above notation, we have

$$\mathbf{e}'_u \cdot \mathbf{e}''_v - \mathbf{e}''_u \cdot \mathbf{e}'_v = \frac{LN - M^2}{(EG - F^2)^{1/2}}. \tag{13.5}$$

Assuming this for a moment, we compute

$$\int_0^{\ell(\boldsymbol{\gamma})} \boldsymbol{e}' \cdot \dot{\boldsymbol{e}}'' ds = \int_0^{\ell(\boldsymbol{\gamma})} \boldsymbol{e}' \cdot (\dot{u}\boldsymbol{e}''_u + \dot{v}\boldsymbol{e}''_v) ds = \int_{\boldsymbol{\pi}} (\boldsymbol{e}' \cdot \boldsymbol{e}''_u) du + (\boldsymbol{e}' \cdot \boldsymbol{e}''_v) dv.$$

By Green's theorem (see Section 3.2), this can be rewritten as a double integral:

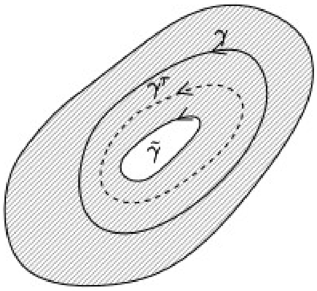
$$\begin{aligned}
\int_0^{\ell(\boldsymbol{\gamma})} \boldsymbol{e}' \cdot \dot{\boldsymbol{e}}'' ds &= \int_{\mathrm{int}(\boldsymbol{\pi})} \{(\boldsymbol{e}' \cdot \boldsymbol{e}''_v)_u - (\boldsymbol{e}' \cdot \boldsymbol{e}''_u)_v\} dudv \\
&= \int_{\mathrm{int}(\boldsymbol{\pi})} \{(\boldsymbol{e}'_u \cdot \boldsymbol{e}''_v) - (\boldsymbol{e}'_v \cdot \boldsymbol{e}''_u)\} dudv \\
&= \int_{\mathrm{int}(\boldsymbol{\pi})} \frac{LN - M^2}{(EG - F^2)^{1/2}} dudv \quad \text{(by Lemma 13.1.3)} \\
&= \int_{\mathrm{int}(\boldsymbol{\pi})} \frac{LN - M^2}{EG - F^2} (EG - F^2)^{1/2} dudv \\
&= \int_{\mathrm{int}(\boldsymbol{\pi})} K d\mathcal{A}_{\boldsymbol{\sigma}} \quad \text{(see Section 6.4).}
\end{aligned} \tag{13.6}$$

If we combine Eqs. 13.4 and 13.6 and compare with the statement of the theorem, we see that what remains is to prove that

$$\int_0^{\ell(\boldsymbol{\gamma})} \dot{\theta}\, ds = 2\pi.$$

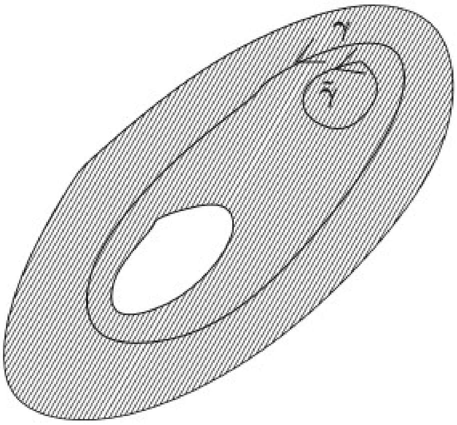
This is a version of Hopf's Umlaufsatz (cf. Theorem 3.1.4). We cannot give a fully satisfactory proof of it here but we offer the following heuristic argument.

The main observation is that, if $\tilde{\boldsymbol{\gamma}}$ is any other simple closed curve contained in the interior of $\boldsymbol{\gamma}$, there is a smooth family of simple closed curves $\boldsymbol{\gamma}^\tau$, defined for $0 \leq \tau \leq 1$, say, with $\boldsymbol{\gamma}^0 = \boldsymbol{\gamma}$ and $\boldsymbol{\gamma}^1 = \tilde{\boldsymbol{\gamma}}$ (see Section 9.4 for the notion of a smooth family of curves). The existence of such a family is supposed to be 'intuitively obvious'.



Note, however, that it is crucial that the interior of $\boldsymbol{\pi}$ is entirely contained in U, otherwise such a family will not exist, in general (see the diagram below).

Observe next that the integral $\int_0^{\ell(\gamma^\tau)} \dot{\theta}\, ds$ should depend continuously on τ. Further, since $\boldsymbol{\gamma}^\tau$ and $\boldsymbol{e}'$ return to their original values as one goes once round $\boldsymbol{\gamma}^\tau$, the integral is always an integer multiple of 2π. These two facts imply that the integral must be independent of τ – for by the intermediate value theorem a continuous variable cannot change from one integer to a different integer without passing through some non-integer value. To compute $\int_0^{\ell(\gamma)} \dot{\theta}\, ds$, we can therefore replace $\boldsymbol{\gamma}$ by any other simple closed curve $\tilde{\boldsymbol{\gamma}}$ in the interior of $\boldsymbol{\gamma}$, since this will not change the value of the integral. We take $\tilde{\boldsymbol{\gamma}}$ to be the image under $\boldsymbol{\sigma}$ of a small circle in the interior of $\boldsymbol{\pi}$. It is 'intuitively clear' that



$$\int_0^{\ell(\tilde{\gamma})} \dot{\theta}\, ds = 2\pi,$$

because

(i) $\boldsymbol{e}'$ is essentially constant at all points of $\tilde{\boldsymbol{\gamma}}$ (because the circle is very small), and

(ii) the tangent vector to $\tilde{\boldsymbol{\gamma}}$ rotates by 2π on going once round $\tilde{\boldsymbol{\gamma}}$ because the interior of $\tilde{\boldsymbol{\gamma}}$ can be considered to be essentially part of a plane, and it is 'intuitively clear' that the tangent vector of a simple closed curve in the plane rotates by 2π on going once round the curve (indeed, this is the content of Theorem 3.1.4).

This completes the 'proof' of Hopf's Umlaufsatz. To complete the proof of Theorem 13.1.2, all that remains is to prove Lemma 13.1.3.

Proof 13.1.3 We can express the partial derivatives of $\boldsymbol{e}'$ and $\boldsymbol{e}''$ with respect to u and v in terms of the orthonormal basis $\{\boldsymbol{e}', \boldsymbol{e}'', \mathbf{N}\}$. Since both partial derivatives of $\boldsymbol{e}'$ are perpendicular to $\boldsymbol{e}'$, the $\boldsymbol{e}'$ components of $\boldsymbol{e}'_u$ and $\boldsymbol{e}'_v$ are zero (and similarly for $\boldsymbol{e}''$). Thus,

$$\begin{aligned}
\boldsymbol{e}'_u &= \qquad\quad \alpha\boldsymbol{e}'' + \lambda'\mathbf{N},\\
\boldsymbol{e}'_v &= \qquad\quad \beta\boldsymbol{e}'' + \mu'\mathbf{N},\\
\boldsymbol{e}''_u &= -\alpha'\boldsymbol{e}' \qquad\quad + \lambda''\mathbf{N},\\
\boldsymbol{e}''_v &= -\beta'\boldsymbol{e}' \qquad\quad + \mu''\mathbf{N},
\end{aligned}$$

for some scalars $\alpha, \beta, \alpha', \beta', \lambda', \mu', \lambda'', \mu''$ (which may depend on u and v). Moreover, by differentiating the equation $\boldsymbol{e}' \cdot \boldsymbol{e}'' = 0$ with respect to u, we see that $\boldsymbol{e}'_u \cdot \boldsymbol{e}'' = -\boldsymbol{e}' \cdot \boldsymbol{e}''_u$. i.e., $\alpha' = \alpha$ (and similarly $\beta' = \beta$). Thus,

$$\begin{aligned}
\boldsymbol{e}'_u &= \qquad\quad \alpha\boldsymbol{e}'' + \lambda'\mathbf{N},\\
\boldsymbol{e}'_v &= \qquad\quad \beta\boldsymbol{e}'' + \mu'\mathbf{N},\\
\boldsymbol{e}''_u &= -\alpha\boldsymbol{e}' \qquad\quad + \lambda''\mathbf{N},\\
\boldsymbol{e}''_v &= -\beta\boldsymbol{e}' \qquad\quad + \mu''\mathbf{N}.
\end{aligned} \tag{13.7}$$

It follows that

$$\boldsymbol{e}'_u \cdot \boldsymbol{e}''_v - \boldsymbol{e}''_u \cdot \boldsymbol{e}'_v = \lambda'\mu'' - \lambda''\mu'. \tag{13.8}$$

On the other hand, combining the formula

$$\mathbf{N}_u \times \mathbf{N}_v = K\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v$$

(see Eq. 8.2) with the formulas

$$\mathbf{N} = \frac{\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v}{\parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel}, \quad \parallel \boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v \parallel = (EG - F^2)^{1/2}$$

(see Proposition 6.4.2), we get

$$\mathbf{N}_u \times \mathbf{N}_v = \frac{LN - M^2}{(EG - F^2)^{1/2}}\mathbf{N},$$

and hence

$$(\mathbf{N}_u \times \mathbf{N}_v) \cdot \mathbf{N} = \frac{LN - M^2}{(EG - F^2)^{1/2}}. \tag{13.9}$$

Since $\mathbf{N} = \boldsymbol{e}' \times \boldsymbol{e}''$,

$$\begin{aligned}(\mathbf{N}_u \times \mathbf{N}_v) \cdot \mathbf{N} &= (\mathbf{N}_u \times \mathbf{N}_v) \cdot (\boldsymbol{e}' \times \boldsymbol{e}''),\\ &= (\mathbf{N}_u \cdot \boldsymbol{e}')(\mathbf{N}_v \cdot \boldsymbol{e}'') - (\mathbf{N}_u \cdot \boldsymbol{e}'')(\mathbf{N}_v \cdot \boldsymbol{e}')\\ &= (\mathbf{N} \cdot \boldsymbol{e}'_u)(\mathbf{N} \cdot \boldsymbol{e}''_v) - (\mathbf{N} \cdot \boldsymbol{e}''_u)(\mathbf{N} \cdot \boldsymbol{e}'_v) \qquad (13.10)\\ &= \lambda'\mu'' - \lambda''\mu' \quad \text{by Eq. 13.7,}\end{aligned}$$

where in passing from the second line to the third we used the equations

$$\begin{aligned}\mathbf{N}_u \cdot \boldsymbol{e}' &= -\mathbf{N} \cdot \boldsymbol{e}'_u, \quad \mathbf{N}_u \cdot \boldsymbol{e}'' = -\mathbf{N} \cdot \boldsymbol{e}''_u,\\ \mathbf{N}_v \cdot \boldsymbol{e}' &= -\mathbf{N} \cdot \boldsymbol{e}'_v, \quad \mathbf{N}_v \cdot \boldsymbol{e}'' = -\mathbf{N} \cdot \boldsymbol{e}''_v,\end{aligned}$$

which follow by differentiating $\mathbf{N} \cdot \boldsymbol{e}' = 0 = \mathbf{N} \cdot \boldsymbol{e}''$ with respect to u and v. Putting Eqs. 13.9 and 13.10 together shows that the right-hand sides of Eqs. 13.5 and 13.8 are equal. Since Eq. 13.8 has already been established, this proves Eq.13.5. □

EXERCISES

13.1.1 Suppose that a surface patch $\boldsymbol{\sigma}$ has Gaussian curvature ≤ 0 everywhere. Prove that there are no simple closed geodesics on $\boldsymbol{\sigma}$. How do you reconcile this with the fact that the parallels of a circular cylinder are geodesics?

13.1.2 Let $\boldsymbol{\gamma}$ be a unit-speed curve in $\mathbb{R}^3$ with nowhere vanishing curvature. Let $\mathbf{n}$ be the principal normal of $\boldsymbol{\gamma}$, viewed as a curve on S^2, and let s be the arc-length of $\mathbf{n}$. Show that the geodesic curvature of $\mathbf{n}$ is, up to a sign,

$$\frac{d}{ds}\left(\tan^{-1}\frac{\tau}{\kappa}\right),$$

where κ and τ are the curvature and torsion of $\boldsymbol{\gamma}$. Show also that, if $\mathbf{n}$ is a *simple closed* curve on S^2, the interior and exterior of $\mathbf{n}$ are regions of equal area (*Jacobi's Theorem*).

5- 6 2 //3

13.2 Gauss–Bonnet for curvilinear polygons

For the next version of Gauss–Bonnet, we shall have to generalize our notion of a curve by allowing the possibility of ' corners'. More precisely, we make the following definition.

Definition 13.2.1

A *curvilinear polygon* in $\mathbb{R}^2$ is a continuous map $\boldsymbol{\pi} : \mathbb{R} \to \mathbb{R}^2$ such that, for some real number T and some points $0 = t_0 < t_1 < \cdots < t_n = T$:

(i) $\boldsymbol{\pi}(t) = \boldsymbol{\pi}(t')$ if and only if $t' - t$ is an integer multiple of T.

(ii) $\boldsymbol{\pi}$ is smooth on each of the open intervals $(t_0, t_1), (t_1, t_2), \ldots, (t_{n-1}, t_n)$.

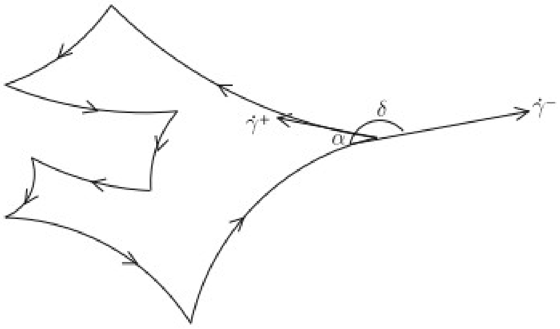
(iii) The one-sided derivatives

$$\dot{\boldsymbol{\pi}}^-(t_i) = \lim_{t \uparrow t_i} \frac{\boldsymbol{\pi}(t) - \boldsymbol{\pi}(t_i)}{t - t_i}, \quad \dot{\boldsymbol{\pi}}^+(t_i) = \lim_{t \downarrow t_i} \frac{\boldsymbol{\pi}(t) - \boldsymbol{\pi}(t_i)}{t - t_i} \tag{13.11}$$

exist for $i = 1, \ldots, n$ and are non-zero and not parallel.

The points $\boldsymbol{\gamma}(t_i)$ for $i = 1, \ldots, n$ are called the *vertices* of the curvilinear polygon $\boldsymbol{\pi}$, and the segments of it corresponding to the open intervals (t_{i-1}, t_i) are called its *edges*.

It makes sense to say that a curvilinear polygon $\boldsymbol{\pi}$ is positively-oriented: for all t such that $\boldsymbol{\pi}(t)$ is not a vertex, the vector $\mathbf{n}_s$ obtained by rotating $\dot{\boldsymbol{\pi}}$ anticlockwise by $\pi/2$ should point into $\operatorname{int}(\boldsymbol{\pi})$. (The region $\operatorname{int}(\boldsymbol{\pi})$ enclosed by $\boldsymbol{\pi}$ makes sense because the Jordan Curve Theorem applies to curvilinear polygons in the plane.)



Now let $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ be a surface patch and let $\boldsymbol{\pi} : \mathbb{R} \to U$ be a curvilinear polygon in U, as in Definition 13.2.1. Then, $\boldsymbol{\gamma} = \boldsymbol{\sigma} \circ \boldsymbol{\pi}$ is called a curvilinear polygon on the surface patch $\boldsymbol{\sigma}$, $\operatorname{int}(\boldsymbol{\gamma})$ is the image under $\boldsymbol{\sigma}$ of $\operatorname{int}(\boldsymbol{\pi})$, the vertices of $\boldsymbol{\gamma}$ are the points $\boldsymbol{\gamma}(t_i)$ for $i = 1, \ldots, n$, and the edges of $\boldsymbol{\gamma}$ are the segments of it corresponding to the open intervals (t_{i-1}, t_i). Since $\boldsymbol{\sigma}$ is allowable, the one-sided derivatives

$$\dot{\boldsymbol{\gamma}}^-(t_i) = \lim_{t\uparrow t_i} \frac{\boldsymbol{\gamma}(t)-\boldsymbol{\gamma}(t_i)}{t-t_i}, \quad \dot{\boldsymbol{\gamma}}^+(t_i) = \lim_{t\downarrow t_i} \frac{\boldsymbol{\gamma}(t)-\boldsymbol{\gamma}(t_i)}{t-t_i}$$

exist and are not parallel.

Let $\theta_i^{\pm}$ be the angles between $\dot{\boldsymbol{\gamma}}^{\pm}(t_i)$ and $\boldsymbol{e}'$, defined as in Eq. 13.1, let $\delta_i = \theta_i^+ - \theta_i^-$ be the external angle at the vertex $\boldsymbol{\gamma}(t_i)$, and let $\alpha_i = \pi - \delta_i$ be the internal angle. Since the tangent vectors $\dot{\boldsymbol{\gamma}}^+(t_i)$ and $\dot{\boldsymbol{\gamma}}^-(t_i)$ are not parallel, the angle δ_i is not a multiple of π. Note that all of these angles are well defined only up to multiples of 2π. We assume from now on that $0 < \alpha_i < 2\pi$ for $i = 1, \ldots, n$.

A curvilinear polygon $\boldsymbol{\gamma}$ is said to be unit-speed if $\parallel \dot{\boldsymbol{\gamma}} \parallel = 1$ whenever $\dot{\boldsymbol{\gamma}}$ is defined, i.e., for all t such that $\boldsymbol{\gamma}(t)$ is not a vertex of $\boldsymbol{\gamma}$. We denote the parameter of $\boldsymbol{\gamma}$ by s if $\boldsymbol{\gamma}$ is unit-speed. The period of $\boldsymbol{\gamma}$ is then equal to its length $\ell(\boldsymbol{\gamma})$, which is the sum of the lengths of the edges of $\boldsymbol{\gamma}$.

Theorem 13.2.2

Let $\boldsymbol{\gamma}$ be a positively-oriented unit-speed curvilinear polygon with n edges on a surface $\boldsymbol{\sigma}$, and let $\alpha_1, \alpha_2, \ldots, \alpha_n$ be the interior angles at its vertices. Then,

$$\int_0^{\ell(\boldsymbol{\gamma})} \kappa_g ds = \sum_{i=1}^n \alpha_i - (n-2)\pi - \int_{\mathrm{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}}.$$

Proof

Exactly the same argument as in the proof of Theorem 13.1.2 shows that

$$\int_0^{\ell(\boldsymbol{\gamma})} \kappa_g ds = \int_0^{\ell(\boldsymbol{\gamma})} \dot{\theta} ds - \int_{\mathrm{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}}.$$

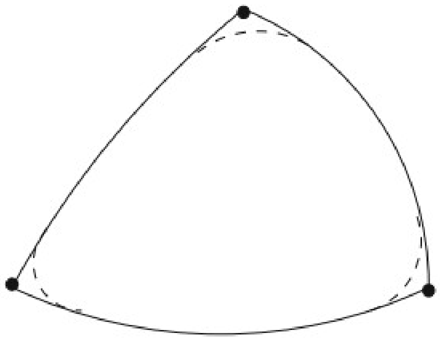
We shall prove that

$$\int_0^{\ell(\boldsymbol{\gamma})} \dot{\theta} ds = 2\pi - \sum_{i=1}^n \delta_i. \tag{13.12}$$

Assuming this, we get

$$\begin{aligned}\int_0^{\ell(\boldsymbol{\gamma})} \kappa_g ds &= 2\pi - \sum_{i=1}^n \delta_i - \int_{\mathrm{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}} \\ &= 2\pi - \sum_{i=1}^n (\pi - \alpha_i) - \int_{\mathrm{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}} \\ &= \sum_{i=1}^n \alpha_i - (n-2)\pi - \int_{\mathrm{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}}.\end{aligned}$$

To establish Eq. 13.12, we imagine 'smoothing' each vertex of $\boldsymbol{\gamma}$ as shown in the following diagram.



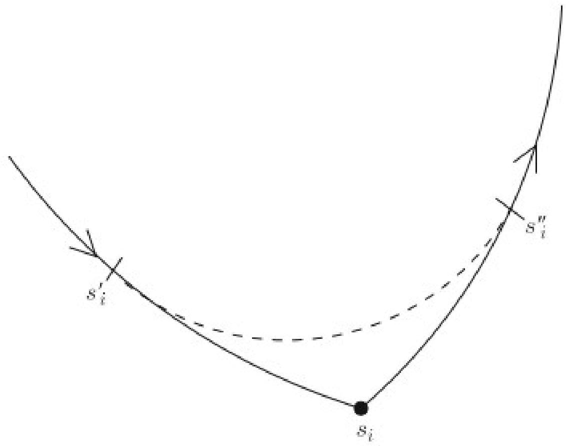
If the 'smoothed' curve $\tilde{\boldsymbol{\gamma}}$ is smooth (!), then, in an obvious notation,

$$\int_0^{\ell(\tilde{\boldsymbol{\gamma}})} \tilde{\dot{\theta}} ds = 2\pi. \tag{13.13}$$

Since $\boldsymbol{\gamma}$ and $\tilde{\boldsymbol{\gamma}}$ are the same except near the vertices of $\boldsymbol{\gamma}$, the difference

$$\int_0^{\ell(\tilde{\boldsymbol{\gamma}})} \tilde{\dot{\theta}} ds - \int_0^{\ell(\boldsymbol{\gamma})} \dot{\theta} ds \tag{13.14}$$

is a sum of n contributions, one from near each vertex. Near $\boldsymbol{\gamma}(s_i)$, the picture is



i.e., $\boldsymbol{\gamma}$ and $\tilde{\boldsymbol{\gamma}}$ agree except when s belongs to a small interval (s_i', s_i''), say, containing s_i, so the contribution from the ith vertex is

$$\int_{s_i'}^{s_i''} \tilde{\dot{\theta}} ds - \int_{s_i'}^{s_i} \dot{\theta} ds - \int_{s_i}^{s_i''} \dot{\theta} ds.$$

The first integral is the angle between $\dot{\tilde{\boldsymbol{\gamma}}}(s_i'')$ and $\dot{\tilde{\boldsymbol{\gamma}}}(s_i')$, which as s_i' and s_i'' tend to s_i becomes the angle between $\dot{\boldsymbol{\gamma}}^+(s_i)$ and $\dot{\boldsymbol{\gamma}}^-(s_i)$, i.e., δ_i. On the other hand, since $\boldsymbol{\gamma}(s)$ is smooth on each of the intervals (s_i', s_i) and (s_i, s_i''), the last two integrals go to zero as s_i' and s_i'' tend to s_i. Thus, the contribution to the expression (13.14) from the ith vertex tends to δ_i as s_i' and s_i'' tend to s_i . Summing over all the vertices, we get

$$\int_0^{\ell(\tilde{\boldsymbol{\gamma}})} \dot{\tilde{\theta}} ds - \int_0^{\ell(\boldsymbol{\gamma})} \dot{\theta} ds = \sum_{i=1}^{n} \delta_i.$$

Equation 13.12 now follows from this and Eq. 13.13. □

Corollary 13.2.3

If $\boldsymbol{\gamma}$ is a curvilinear polygon with n edges each of which is an arc of a geodesic, then the internal angles $\alpha_1, \alpha_2, \ldots, \alpha_n$ of the polygon satisfy the equation

$$\sum_{i=1}^{n} \alpha_i = (n-2)\pi + \int_{\operatorname{int}(\boldsymbol{\gamma})} K d\mathcal{A}_{\boldsymbol{\sigma}}.$$

Proof

This is immediate from Theorem 13.2.2, since $\kappa_g = 0$ along a geodesic. □

As a special case of Corollary 13.2.3, consider an n-gon in the plane with straight edges. Since $K = 0$ for the plane, Corollary 13.2.3 gives

$$\sum_{i=1}^{n} \alpha_i = (n-2)\pi,$$

a well-known result of elementary geometry.

For a curvilinear n-gon on S^2 whose sides are arcs of great circles, we have $K = 1$ so $\sum \alpha_i$ exceeds the plane value $(n-2)\pi$ by the area $\int d\mathcal{A}_{\boldsymbol{\sigma}}$ of the polygon. Taking $n = 3$, we get for the area of a spherical triangle with angles α, β, γ whose edges are arcs of great circles,

$$\mathcal{A} = \alpha + \beta + \gamma - \pi.$$

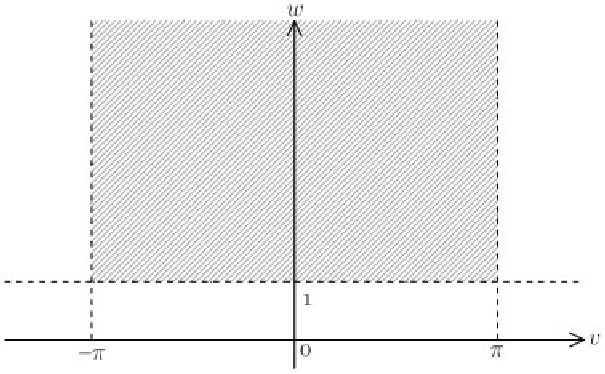
This is just Theorem 6.4.7, which is therefore a special case of Gauss–Bonnet.

Finally, for a geodesic n-gon on the pseudosphere (see Section 8.3), for which $K = -1$, we see that $\sum \alpha_i$ is *less* than $(n-2)\pi$ by the area of the polygon:

$$\mathcal{A} = (n-2)\pi - \alpha_1 - \alpha_2 - \cdots - \alpha_n,$$

which is Theorem 11.1.5.

5- 6 726/ 3

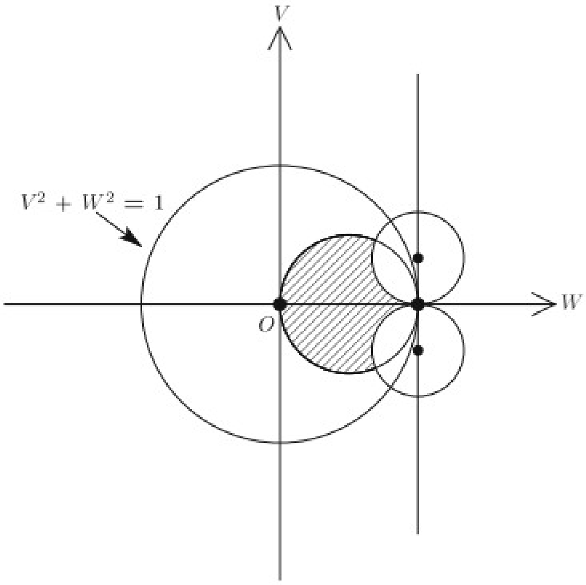


8.3.1 (i) Setting $\tilde{u} = v, \tilde{v} = w = e^{-u}$, we have $u = -\ln\tilde{v}, v = \tilde{u}$ so, in the notation of Exercise 6.1.4, $J = \begin{pmatrix} 0 & -\frac{1}{\tilde{v}} \\ 1 & 0 \end{pmatrix}$. Since J is invertible, $(u, v) \mapsto (v, w)$ is a reparametrization map. The first fundamental form in terms of v, w is given by $\begin{pmatrix} \tilde{E} & \tilde{F} \\ \tilde{F} & \tilde{G} \end{pmatrix} = J^t \begin{pmatrix} E & F \\ F & G \end{pmatrix} J = \begin{pmatrix} 0 & 1 \\ -\frac{1}{\tilde{v}} & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & f(u)^2 \end{pmatrix} \begin{pmatrix} 0 & -\frac{1}{\tilde{v}} \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} \frac{1}{w^2} & 0 \\ 0 & \frac{1}{w^2} \end{pmatrix}$, so the first fundamental form is $(dv^2 + dw^2)/w^2$.

(ii) We find that the matrix $\tilde{J} = \begin{pmatrix} \frac{\partial v}{\partial V} & \frac{\partial v}{\partial W} \\ \frac{\partial w}{\partial V} & \frac{\partial w}{\partial W} \end{pmatrix} = \begin{pmatrix} v(w+1) & \frac{1}{2}(v^2 - (w+1)^2) \\ -\frac{1}{2}(v^2 - (w+1)^2) & v(w+1) \end{pmatrix}$, so the first fundamental form matrix in terms of V and W is $\tilde{J}^t \begin{pmatrix} \frac{1}{w^2} & 0 \\ 0 & \frac{1}{w^2} \end{pmatrix} \tilde{J} = \frac{(v^2+(w+1)^2)^2}{4w^2} I = \frac{4}{(1-V^2-W^2)^2} I$, after some tedious algebra.

In (i), $u < 0$ and $-\pi < v < \pi$ corresponds to $-\pi < v < \pi$ and $w > 1$, a semi-infinite rectangle in the upper half of the vw-plane.

To find the corresponding region in (ii), it is convenient to introduce the complex numbers $z = v + iw$, $Z = V + iW$. Then, the equations in (ii) are equivalent to $Z = \frac{z-i}{z+i}$, $z = \frac{Z+1}{i(Z-1)}$. The line $v = \pi$ in the vw-plane corresponds to $z + \bar{z} = 2\pi$ (the bar denoting complex conjugate), i.e., $\frac{Z+1}{i(Z-1)} - \frac{\bar{Z}+1}{i(\bar{Z}-1)} = 2\pi$, which simplifies to $|Z - (1 - \frac{i}{\pi})|^2 = \frac{1}{\pi^2}$; so $v = \pi$ corresponds to the circle in the VW-plane with centre $1 - \frac{i}{\pi}$ and radius $\frac{1}{\pi}$. Similarly, $v = -\pi$ corresponds to the circle with centre $1 + \frac{i}{\pi}$ and radius $\frac{1}{\pi}$. Finally, $w = 1$ corresponds to $z - \bar{z} = 2i$, i.e., $\frac{Z+1}{i(Z-1)} + \frac{\bar{Z}+1}{i(\bar{Z}-1)} = 2i$. This simplifies to $|Z - \frac{1}{2}|^2 = \frac{1}{4}$; so $w = 1$ corresponds to the circle with centre $1/2$ and radius $1/2$ in the VW-plane. The required region in the VW-plane is that bounded by these three circles:



For (iii) we follow the hint and make use of polar coordinates on the disc, $V = r\cos\theta$, $W = r\sin\theta$, $\bar{V} = \bar{r}\cos\bar{\theta}$, $\bar{W} = \bar{r}\sin\bar{\theta}$. We find that $\bar{r} = \frac{2r}{r^2+1}$, $\bar{\theta} = \theta$. Suppose that the first fundamental form in terms of these parameters is $Ed\bar{r}^2 + 2Fd\bar{r}d\bar{\theta} + Gd\bar{\theta}^2$. Since $\frac{d\bar{r}}{dr} = \frac{2(1-r^2)}{(1+r^2)^2}$, the first fundamental form is $\frac{4(1-r^2)^2}{(1+r^2)^4}Edr^2 + \frac{4(1-r^2)}{(1+r^2)^2}Fdrd\theta + Gd\theta^2$. Equating this to $\frac{4(dV^2+dW^2)}{(1-V^2-W^2)^2} = \frac{4(dr^2+r^2d\theta^2)}{(1-r^2)^2}$, we get $E = \frac{(1+r^2)^4}{(1-r^2)^4} = \frac{1}{(1-\bar{r}^2)^2}$, $F = 0$, $G = \frac{4r^2}{(1-r^2)^2} = \frac{\bar{r}^2}{1-\bar{r}^2}$. Converting back to the parameters $(\bar{V}, \bar{W})$, we have $\bar{r}d\bar{r} = \bar{V}d\bar{V} + \bar{W}d\bar{W}, \bar{r}^2 d\bar{\theta} = \bar{V}d\bar{W} - \bar{W}d\bar{V}$, so the first fundamental form becomes $\frac{(\bar{V}d\bar{V}+\bar{W}d\bar{W})^2+(1-\bar{r}^2)(\bar{V}d\bar{W}-\bar{W}d\bar{V})^2}{\bar{r}^2(1-\bar{r}^2)^2} =$ $\frac{(\bar{V}^2+(1-\bar{r}^2)\bar{W}^2)d\bar{V}^2+2\bar{r}^2\bar{V}\bar{W}d\bar{V}d\bar{W}+(\bar{W}^2+(1-\bar{r}^2)\bar{V}^2)d\bar{W}^2}{\bar{r}^2(1-\bar{r}^2)^2}$
$= \frac{(1-\bar{W}^2)d\bar{V}^2+2\bar{V}\bar{W}d\bar{V}d\bar{W}+(1-\bar{V}^2)d\bar{W}^2}{(1-\bar{V}^2-\bar{W}^2)^2}$.

8.4.1 Let $\tilde{\boldsymbol{\sigma}}(\tilde{u}, \tilde{v})$ be a patch of $\mathcal{S}$ containing $\mathbf{p} = \tilde{\boldsymbol{\sigma}}(\tilde{u}_0, \tilde{v}_0)$. The Gaussian curvature K of $\mathcal{S}$ is < 0 at $\mathbf{p}$; since K is a smooth function of $(\tilde{u}, \tilde{v})$ (Exercise 8.1.3), $K(\tilde{u}, \tilde{v}) < 0$ for $(\tilde{u}, \tilde{v})$ in some open set $\tilde{U}$ containing $(\tilde{u}_0, \tilde{v}_0)$; then every point of $\tilde{\boldsymbol{\sigma}}(\tilde{U})$ is hyperbolic. Let κ_1, κ_2 be the principal curvatures of $\tilde{\boldsymbol{\sigma}}$, let $0 < \theta < \pi/2$ be such that $\tan\theta = \sqrt{-\kappa_1/\kappa_2}$, and let $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ be the unit tangent vectors of $\tilde{\boldsymbol{\sigma}}$ making angles θ and $-\theta$, respectively, with the principal vector corresponding to κ_1 (see Theorem 8.2.4). Applying Proposition 8.4.3 gives the result. For the last part, put $\dot{v} = 0$ in the formula for κ_n in Proposition 7.3.5: this shows that $L = 0$ if the parameter curves $v =$ constant are asymptotic. Similarly $N = 0$ if the parameter curves $u =$ constant are asymptotic.

and write down those, if any, that satisfy the equation. However, it may be hard in practice, because there are 2^m sequences of values for m variables (two for the first variable; for each of these, two for the second variable; and so on). So the number of possibilities quickly becomes astronomical as m increases. And no known method for solving m-variable equations, mod 2, is substantially faster than trying all possibilities.

In fact, no fast method is known to decide even *existence* of solutions for m-variable equations, mod 2. This is a fundamental unsolved problem in computation and logic, as we will explain further in chapters 3 and 9.

2.5 Quadratic Integers

Let us begin with a curious fact about the numbers 25 and 27. 25 is a square and 27 is a cube, so these numbers give a solution of the equation $y^3 = x^2 + 2$; namely, $x = 5$ and $y = 3$. Nearly 2000 years ago, Diophantus specifically mentioned this equation and this solution in his *Arithmetica*, Book VI, Problem 17. After reading this passage in Diophantus, Fermat (1657) claimed that it is the *only* solution in the positive integers. Why the equation caught their attention we do not really know. But it was a turning point in the development of number theory when Euler (1770), p. 401, proved Fermat's claim by a new and audacious method.

Observing that $x^2 + 2 = (x + \sqrt{-2})(x - \sqrt{-2})$, Euler's attention was drawn to numbers of the form $a + b\sqrt{-2}$, where a and b are integers. Leaving aside the meaning of the "imaginary" $\sqrt{-2}$, these new numbers are also "integers" in some sense. This is because the sum, difference, and product of any two of them is another number of the same kind and they satisfy the algebraic rules of a ring (mentioned in section 1.3). The audacious part of Euler's solution was to assume that they also have more doubtful properties, such as unique prime factorization. To see why this assumption comes up, we follow Euler's train of thought.

Assume that x and y are ordinary integers such that

$$y^3 = x^2 + 2 = (x + \sqrt{-2})(x - \sqrt{-2}).$$

Then one might think, if the factors on the right behave like ordinary integers, that $\gcd(x+\sqrt{-2}, x-\sqrt{-2})=1$ and (imagining $x+\sqrt{-2}$ and $x-\sqrt{-2}$ factorized into primes, with no prime common to both) that each of them is a cube, since their product is the cube y^3. This is not quite right, but it is true when x is a solution of $y^3=x^2+2$, as we will see in the next subsection.

Then, writing $x+\sqrt{-2}$ as a cube, we get

$$\begin{aligned} x+\sqrt{-2} &= (a+b\sqrt{-2})^3 \\ &= a^3+3a^2\cdot b\sqrt{-2}+3a\cdot(b\sqrt{-2})^2+(b\sqrt{-2})^3 \\ &= a^3-6ab^2+(3a^2b-2b^3)\sqrt{-2}. \end{aligned}$$

It follows, by equating "real and imaginary parts," that

$$x=a^3-6ab^2 \quad \text{and} \quad 1=3a^2b-2b^3=b(3a^2-2b^2).$$

Now if $1=b(3a^2-2b^2)$ then b divides 1 and therefore $b=\pm1$. If $b=-1$ then $1=-(3a^2-2)$, which is impossible because $3a^2-2$ is either -2 (for $a=0$) or positive. We must therefore have $b=1$, in which case $1=3a^2-2$. So $a^2=1$ and hence $a=\pm1$.

Substituting $a=1$, $b=1$ in $x=a^3-6ab^2$ gives the negative value $x=-5$, so the only remaining option is $a=-1$, $b=1$. This gives the value $x=5$ claimed by Fermat, and with it the value $y=3$.

What Is Going on in Euler's Proof?

Euler came up with his proof before the "imaginary" number $\sqrt{-2}$ was well understood, not to mention the concept of the "integers" $a+b\sqrt{-2}$ and their greatest common divisors and primes. Today we know that it is valid to picture $a+b\sqrt{-2}$ as a point in the plane with real coordinate a and imaginary coordinate $b\sqrt{2}$, so that the distance of this point from the origin is $\sqrt{a^2+2b^2}$, by the Pythagorean theorem (figure 2.3). We also call this distance the *absolute value* of $a+b\sqrt{-2}$, and denote it by $|a+b\sqrt{-2}|$.

The square $|a+b\sqrt{-2}|^2$ of this distance is the ordinary integer a^2+2b^2, which is called the *norm* of $a+b\sqrt{-2}$. With its help we can

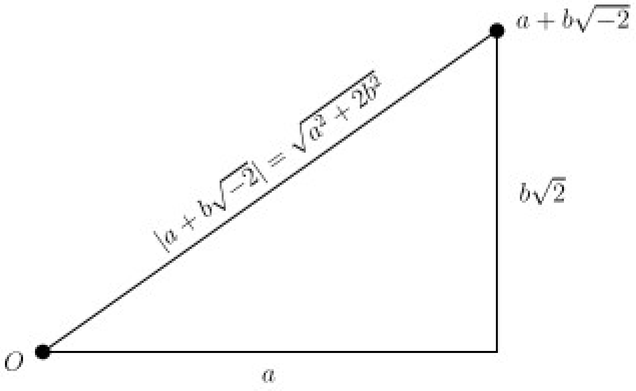

Figure 2.3: Distance to the point $a + b\sqrt{-2}$.

reduce questions about divisibility of these *quadratic integers* to questions about divisibility in the ordinary integers. The magical property of the norm that makes this possible is

$$|uv|^2 = |u|^2|v|^2, \tag{*}$$

or "norm of a product equals the product of the norms." We say more about this *multiplicative property* in the next section, but we first explain how it enables us to prove that $\gcd(x + \sqrt{-2}, x - \sqrt{-2}) = 1$ when x and y are integers such that $y^3 = x^2 + 2$.

The magical property (*) means that if v divides w (which means in turn that $w = uv$ for some u) then $|v|^2$ divides $|w|^2$. Also, the only numbers $a + b\sqrt{-2}$ with norm 1 are ±1, because $a^2 + 2b^2 = 1$ only if $a = \pm 1$, $b = 0$. Thus it suffices to prove that *any* common divisor of $x + \sqrt{-2}$, $x - \sqrt{-2}$ has norm 1 when $y^3 = x^2 + 2$.

First notice that

$$y^3 \equiv 0,\ 1,\ \text{or } 3 \pmod 4.$$

This can be seen by cubing the four possible values of y mod 4, namely 0, 1, 2, 3. On the other hand, for the even values of x mod 4 (0 and 2) we have

$$x^2 + 2 \equiv 2 \pmod 4.$$

So $y^3 = x^2 + 2$ only for x odd, and then the norm $x^2 + 2$ of $x \pm \sqrt{-2}$ is odd.

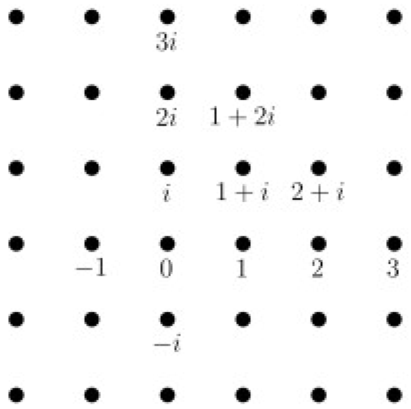

Figure 2.4: Gaussian integers near 0.

Now a divisor of $x + \sqrt{-2}$ and $x - \sqrt{-2}$ also divides their difference $2\sqrt{-2}$, which has norm 8. The gcd of the norms 8 and the odd number $x^2 + 2$ is 1, so any divisor of $x + \sqrt{-2}$, $x - \sqrt{-2}$ is a number whose norm divides 1; that is, 1 itself.

2.6 The Gaussian Integers

In the previous section we saw how a problem about ordinary integers draws our attention to weird "integers" involving the quantity $\sqrt{-2}$. Moreover, if we play along with these weird integers—granting them attributes such as gcd and primes—they enable us to solve the original problem very simply. It seems as though the factorization $x^2 + 2 = (x + \sqrt{-2})(x - \sqrt{-2})$ explains the behavior of $x^2 + 2$ better than we can in the language of ordinary integers.

However, we have yet to make sense of the concept of "prime" and "unique prime factorization" in the world of the quadratic integers $a + b\sqrt{-2}$. To pave the way for this, we look first at the simplest quadratic integers: those of the form $a + b\sqrt{-1}$, or $a + bi$, where a and b are ordinary integers. These are called the *Gaussian integers* because they were first studied by Gauss (1832). The Gaussian integers form a square grid in the plane of complex numbers, part of which is shown in figure 2.4.

Like the integers $a+b\sqrt{-2}$, the Gaussian integers form a ring because the sum, difference, and product of Gaussian integers are again Gaussian integers, and the various algebraic laws are easily checked. The distance from the origin to $a+bi$ (also known as the *absolute value*, $|a+bi|$) is $\sqrt{a^2+b^2}$ by the Pythagorean theorem, and the square of this distance, a^2+b^2, is an ordinary integer called the *norm* of $a+bi$. Again it is true that "the norm of a product equals the product of the norms," but this time we will check.

Consider Gaussian integers $a+bi$ and $c+di$, whose norms $|a+bi|^2$ and $|c+di|^2$ are a^2+b^2 and c^2+d^2, respectively. Their product is

$$\begin{aligned}(a+bi)(c+di) &= ac+adi+bci+bdi^2\\ &= (ac-bd)+(ad+bc)i \quad \text{because} \quad i^2=-1.\end{aligned}$$

It follows that the norm of the product is $(ac-bd)^2+(ad+bc)^2$, and miraculously

$$(ac-bd)^2+(ad+bc)^2=(a^2+b^2)(c^2+d^2)$$

—the product of the norms. This identity can be checked by multiplying out both sides, and finding that they both equal $a^2c^2+a^2d^2+b^2c^2+b^2d^2$.

Notice that this calculation does not assume that a, b, c, d are integers, so in fact it is true for any complex numbers u, v that

$$|uv|^2=|u|^2|v|^2.$$

This is why "norm of a product equals product of the norms" is also true for the integers $a+b\sqrt{-2}$.[1] As for the latter integers, it follows for the Gaussian integers that if v divides w then $|v|^2$ divides $|w|^2$, so divisibility of Gaussian integers depends on divisibility of ordinary integers.

It now makes sense for us to define a *Gaussian prime* to be a Gaussian integer, of norm greater than 1, which is not the product of

---

[1] It also follows that $|uv|=|u||v|$, a fact which has some geometric implications for the complex numbers, as we will see in section 10.3.

Gaussian integers of smaller norm. Since norms are ordinary integers, the process of factorizing a Gaussian integer into Gaussian integers of smaller norm must eventually halt, necessarily with Gaussian primes. So *every Gaussian integer has a Gaussian prime factorization.*

Examples of Gaussian Prime Factorizations

The smallest example is $2 = (1+i)(1-i)$. This is a factorization into numbers of smaller norm, because $|1+i|^2 = |1-i|^2 = 2$ and $|2|^2 = 4$. Also, neither $1+i$ nor $1-i$ can be split into factors of smaller norm, because their norm 2 is not the product of smaller integers.

It is the same story for any ordinary prime that is the sum of two squares, such as $37 = 6^2 + 1^2$. The ordinary prime splits into Gaussian factors of smaller norm, in this case

$$6^2 + 1^2 = (6+i)(6-i), \quad \text{where} \quad |6+i|^2 = |6-i|^2 = 37,$$
$$\text{whereas} \quad |37|^2 = 37^2.$$

But neither factor splits into factors of smaller norm, because 37 is not a product of smaller ordinary integers. Thus any ordinary prime that is a sum of two squares is a product of two Gaussian primes.

If we are given a random Gaussian integer, such as $3+i$, we can find its Gaussian prime factors from the ordinary prime factors of its norm. In this case

$$|3+i|^2 = 3^2 + 1^2 = 10 = 2 \cdot 5.$$

Thus we are looking for Gaussian factors of norms 2 and 5, and they will necessarily be Gaussian primes because their norms are ordinary primes. We already know some Gaussian primes of norm 2; namely, $1+i$ and $1-i$. Apart from changing the sign of 1, these are the only ones. And the only Gaussian primes of norm 5 are $2+i$ and similar numbers obtained by changing signs (since the only squares with sum 5 are 4 and 1). Among this small number of possibilities, we soon find that

$$3+i = (1-i)(2+i).$$

Division with Remainder

We now consider a rather different problem: *division with remainder*. For ordinary integers we have the visually evident *division property* that $a = qb + r$ with $|r| < |b|$, as we saw in section 2.1. Given a Gaussian integer, say $5 + 3i$, and a Gaussian integer of smaller norm, say $3 + i$, we would like to be able to divide $5 + 3i$ by $3 + i$ and obtain a remainder r of smaller norm than $3 + i$. This means finding Gaussian integers q and r ("quotient" and "remainder") with

$$5 + 3i = (3 + i)q + r, \quad \text{such that} \quad |r| < |3 + i|.$$

This can be done by looking at the multiples $3 + i$ in the neighborhood of $5 + 3i$, and picking the one, $(3 + i)q$, nearest to $5 + 3i$. Then the difference

$$r = 5 + 3i - (3 + i)q$$

is as small as possible, and hopefully it is smaller than $3 + i$.

Indeed, this always works, and for a rather striking reason: *the multiples of $3 + i$ form a grid of squares of side $|3 + i|$, and the distance from any point in a square to the nearest corner is less than the length of the side.*

Why squares? Well, any Gaussian integer multiple of $3 + i$, by $a + bi$ say, is the sum of a copies of $3 + i$ and b copies of $i(3 + i) = -1 + 3i$. The points $3 + i$ and $-1 + 3i$ lie at distance $|3 + 1| = \sqrt{10} = |-1 + 3i|$ from 0, and *in perpendicular directions*. Thus the points 0, $3 + i$, and $i(3 + i) = -1 + 3i$ form two sides of a square. Adding further copies of $3 + i$ and $-1 + 3i$ creates further squares, all of side length $|3 + i|$, as shown in figure 2.5.

We see from figure 2.5 that the multiple of $3 + i$ nearest to $5 + 3i$ is $2(3 + i)$, and that their difference is

$$r = 2(3 + i) - (5 + 3i) = 1 - i, \quad \text{with absolute value } \sqrt{2} < \sqrt{10}.$$

More generally, it is easy to prove (say, using the Pythagorean theorem) that the distance from any point in a square to the nearest corner is less than the side of the square. Also, the multiples uq of any Gaussian integer u form a grid of squares of side length $|u|$ by

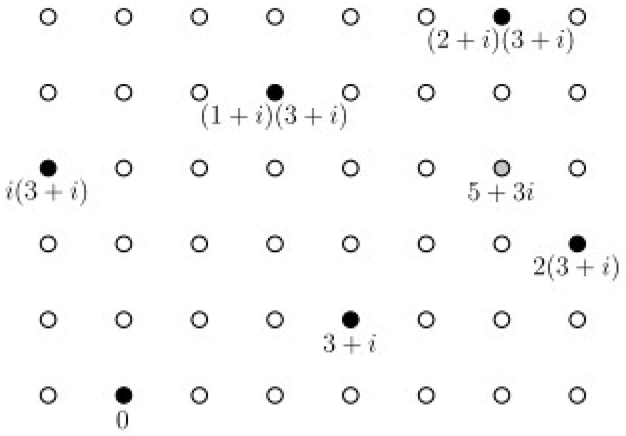

Figure 2.5: Multiples of $3+i$ near $5+3i$.

the argument just used for $u = 3+i$, hence any Gaussian integer v has difference

$$r = v - uq \quad \text{of absolute value } < |u|$$

from some uq. In other words, we have the:

Division property. For any Gaussian integers u, v there are Gaussian integers q, r such that

$$v = uq + r \quad \text{with} \quad |r| < |u|.$$

Since the remainder is smaller than the divisor u, the Euclidean algorithm by repeated division with remainder will terminate for any pair s, t of Gaussian integers, giving us their gcd in the form

$$\gcd(s, t) = ms + nt \quad \text{for some Gaussian integers } m \text{ and } n.$$

Then, by the same trick used for ordinary integers in section 2.3 we can prove:

Prime divisor property. If a Gaussian prime p divides a product uv of Gaussian integers, then p divides u or p divides v.

As we know from section 2.3, *unique prime factorization* now follows. The only difference is that it is slightly “less unique.” This is because, when one Gaussian prime divides another, the quotient is not necessarily 1: it could also be -1 or $\pm i$. For this reason we say that *Gaussian prime factorization is unique up to factors of* ± 1 *and* $\pm i$.

2.7 Euler's Proof Revisited

Now we know how to talk about "primes" among the integers $a + b\sqrt{-2}$ brought to light in Euler's solution of $y^3 = x^2 + 2$.

We measure the size of $a + b\sqrt{-2}$ by its norm $|a + b\sqrt{-2}|^2 = a^2 + 2b^2$, and say that $a + b\sqrt{-2}$ is *prime* if its norm is greater than 1 and $a + b\sqrt{-2}$ is not the product of integers of smaller norm. (Incidentally, the only integers $a + b\sqrt{-2}$ of norm 1 are ± 1, because $a^2 + 2b^2 = 1$ only for $a = \pm 1$ and $b = 0$.)

We also know that we can prove unique prime factorization for the integers $a + b\sqrt{-2}$ if we can prove the *division property*: for any integers u, v of the form $a + b\sqrt{-2}$ there are integers q, r (also of this form) such that

$$v = uq + r \quad \text{with} \quad |r| < |u|.$$

And we know how to find q and r: look at the multiples uq of u, and let

$$r = v - (\text{multiple } uq \text{ nearest to } v).$$

Thus it remains only to get a view of the multiples of u—clear enough that we can see that r is smaller than u.

As with the Gaussian integers, we will illustrate the idea with a particular example: in this case $u = 1 + \sqrt{-2}$, $v = 5 + \sqrt{-2}$. Figure 2.6 shows some of the relevant points in the plane of complex numbers.

The integers $a + b\sqrt{-2}$ form a grid of rectangles of width 1 and height $\sqrt{2}$. The multiples of $1 + \sqrt{-2}$ form a grid of rectangles of the *same shape*, but magnified by $|1 + \sqrt{-2}| = \sqrt{5}$ and rotated so that their short sides lie in the direction of $1 + \sqrt{-2}$.

The multiple of $1 + \sqrt{-2}$ nearest to $5 + \sqrt{-2}$ is

$$(2 - \sqrt{-2})(1 + \sqrt{-2}) = 4 + \sqrt{-2},$$

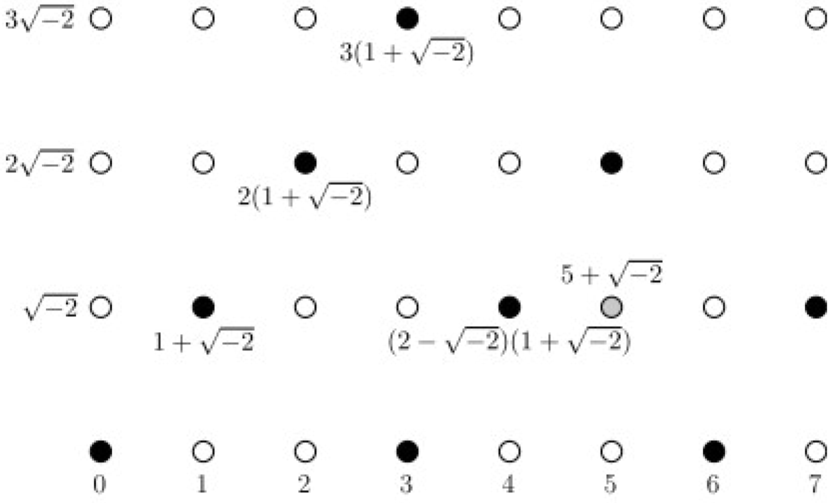

Figure 2.6: Multiples of $1+\sqrt{-2}$ near $5+\sqrt{-2}$.

so we get $q = 2 - \sqrt{-2}$ and $r = 1$. This r is certainly of smaller absolute value than the divisor $1+\sqrt{-2}$.

In general, the multiples of an integer $u = a + b\sqrt{-2}$ form a grid of rectangles of the same shape as the original grid, but magnified by $|u|$ and rotated so that their short sides are in the direction of u. Since the size $|r|$ of the remainder is the distance from v to the nearest multiple of u, it remains to show that *in a rectangle with short side* $|u|$ *and long side* $\sqrt{2}|u|$, *the distance from any point to the nearest corner is less than* $|u|$.

To see why this is true, consider the worst-case scenario shown in figure 2.7, where v is at the center of the rectangle.

By the Pythagorean theorem,

$$|r| = \sqrt{\frac{|u|^2}{2^2} + \frac{|u|^2}{2}} = \sqrt{\frac{3}{4}|u|^2} = \frac{\sqrt{3}}{2}|u| < |u|.$$

This finally proves the division property for the integers $a + b\sqrt{-2}$. As with ordinary and Gaussian integers, this gives the Euclidean algorithm, prime divisor property, and unique prime factorization. In fact, prime factorization is unique up to factors ±1 here, since the only integers $a + b\sqrt{-2}$ of norm 1 are ± 1.

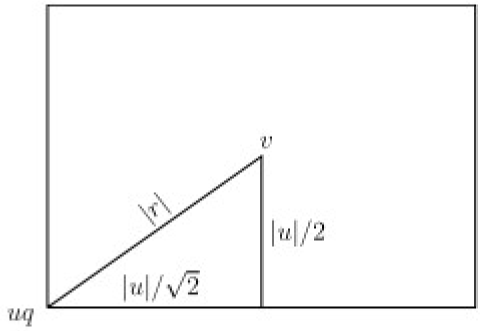

Figure 2.7: The point most distant from the corners.

Now we should recall *why* we want unique prime factorization for the integers $a + b\sqrt{-2}$. In section 2.5 we had

$$y^3 = x^2 + 2 = (x + \sqrt{-2})(x - \sqrt{-2}),$$

and we established that $x + \sqrt{-2}$ and $x - \sqrt{-2}$ have no common prime factor. But each prime factor p in y occurs as p^3 in y^3, so each prime factor p in $x + \sqrt{-2}$ occurs as $\pm p^3 = (\pm p)^3$, and each prime factor q in $x - \sqrt{-2}$ occurs as $\pm q^3 = (\pm q)^3$. In other words, $x + \sqrt{-2}$ *is a product of cubes and hence is a cube itself;* $x - \sqrt{-2}$ *is a product of cubes and hence is a cube itself.*

Euler's calculation and proof, starting with $x + \sqrt{-2} = (a + b\sqrt{-2})^3$, is now justified. The justification is probably far from any Euler had in mind, but it is based on ideas that now belong to elementary mathematics:

- The theory of divisibility and primes, based on the division property and the Euclidean algorithm.
- The multiplicative property of absolute value, $|uv| = |u||v|$, for complex numbers.
- Geometric representation of complex numbers and the Pythagorean theorem.

2.8 $\sqrt{2}$ and the Pell Equation

Another famous equation for which integer solutions are sought is

$$x^2 - 2y^2 = 1. \tag{*}$$

This equation was of interest to the ancient Greeks because, if x and y are large integers satisfying the equation, then x^2/y^2 is very close to 2. This implies that the fraction x/y is very close to $\sqrt{2}$.

In this section we will show that indeed there are arbitrarily large solutions of (*) and we will find a simple algorithm for producing them (and hence for finding arbitrarily close rational approximations to $\sqrt{2}$). We begin with the obvious solution $x = 3$, $y = 2$, which is the smallest positive integer solution.

Now since

$$1 = 3^2 - 2 \cdot 2^2$$

then

$$1 = (3^2 - 2 \cdot 2^2)^n \quad \text{for any positive integer } n.$$

Also,

$$3^2 - 2 \cdot 2^2 = (3 + 2\sqrt{2})(3 - 2\sqrt{2}),$$

so we have

$$1 = (3 + 2\sqrt{2})^n (3 - 2\sqrt{2})^n.$$

This prompts us to look at the positive integers x_n and y_n such that

$$(3 + 2\sqrt{2})^n = x_n + y_n\sqrt{2}. \tag{**}$$

For example,

$$(3 + 2\sqrt{2})^2 = 3^2 + 2 \cdot 3 \cdot 2\sqrt{2} + (2\sqrt{2})^2 = 17 + 12\sqrt{2},$$

so $x_2 = 17$ and $y_2 = 12$. We notice that $x = 17$, $y = 12$ is also a solution of (*).

In fact $x = x_n$, $y = y_n$ is a solution of (*) for each positive integer n. We prove this by induction.

Base step. The statement is true for $n = 1$ because $x_1^2 - 2y_1^2 = 3^2 - 2 \cdot 2^2 = 1$.

Induction step. We prove that if the statement is true for $n = k$ (that is, $x_k^2 - 2y_k^2 = 1$), then it is true for $n = k + 1$. By the definition (**) of x_{k+1} and y_{k+1},

$$\begin{aligned} x_{k+1} + y_{k+1}\sqrt{2} &= (3 + 2\sqrt{2})^{k+1} \\ &= (3 + 2\sqrt{2})^k (3 + 2\sqrt{2}) \\ &= (x_k + y_k\sqrt{2})(3 + 2\sqrt{2}) \\ &\qquad\qquad \text{(by definition of } x_k,\ y_k\text{)} \\ &= 3x_k + 4y_k + (2x_k + 3y_k)\sqrt{2}. \end{aligned}$$

Equating “rational and irrational parts” we get

$$x_{k+1} = 3x_k + 4y_k, \quad y_{k+1} = 2x_k + 3y_k. \tag{***}$$

It follows that

$$\begin{aligned} x_{k+1}^2 - 2y_{k+1}^2 &= (3x_k + 4y_k)^2 - 2(2x_k + 3y_k)^2 \\ &= 9x_k^2 + 24x_k y_k + 16y_k^2 - 2(4x_k^2 + 12x_k y_k + 9y_k^2) \\ &= x_k^2 - 2y_k^2 \\ &= 1, \qquad \text{(by induction hypothesis)} \end{aligned}$$

which completes the induction.

Thus $x_n^2 - 2y_n^2 = 1$ for all positive integers n.

It follows from the equations (***) that x_n and y_n increase with n (in fact, very rapidly). So x_n / y_n rapidly approaches $\sqrt{2}$ as n increases.

The first few approximations are

$$x_1/y_1 = 3/2 = 1.5$$

$$x_2/y_2 = 17/12 = 1.416\cdots$$

$$x_3/y_3 = 99/70 = 1.41428\cdots$$

$$x_4/y_4 = 577/408 = 1.4142156\cdots\ ,$$

which are correct in the first 1, 3, 5, 7 decimal places, respectively.

The Pell Equation

The equation $x^2 - 2y^2 = 1$ is a special case of the equation $x^2 - my^2 = 1$, for a nonsquare positive integer m, called the *Pell equation*. A proof similar to the one above shows that, if $x = x_1$, $y = y_1 \neq 0$ is one solution to the Pell equation, then we can find arbitrarily large solutions $x = x_n$, $y = y_n$ by the formula

$$x_n + y_n\sqrt{m} = (x_1 + y_1\sqrt{m})^n.$$

For example, $x = 2$, $y = 1$ is a solution of $x^2 - 3y^2 = 1$, and we get further solutions by the formula

$$x_n + y_n\sqrt{3} = (2 + \sqrt{3})^n.$$

In particular, using $(2 + \sqrt{3})^2 = 7 + 4\sqrt{3}$, we find the second solution $x = 7$, $y = 4$.

This is easy and fun to do, but two questions present themselves.

- How do we know that a solution of $x^2 - my^2 = 1$ *exists*?
- Given the smallest positive solution $x = x_1$ and $y = y_1$, does

  $$x_n + y_n\sqrt{m} = (x_1 + y_1\sqrt{m})^n$$

  give *all* positive integer solutions?

These questions are most easily answered by importing some ideas from outside number theory (the "pigeonhole principle" and some deeper algebra), so we will defer the answers until section 10.1.

5

Geometry

PREVIEW

Geometry was the first mathematical discipline to be developed in detail, and a large swath of elementary geometry is already in Euclid's *Elements*. The early sections of this chapter sample some of the highlights of Euclid's approach to geometry, which is an attractive blend of visualization and logic. In fact, for many people it is still the most compelling example of mathematical reasoning.

Euclid's geometry is literally "hands on," because it uses hand tools: the *straightedge* and the *compass*. These tools determine the subject matter of Euclid's geometry—straight lines and circles—but this subject matter embraces the measurement of length, area, and angles (and the sometimes unexpected connections between them, such as the Pythagorean theorem).

More surprisingly, Euclid's geometry has a rich *algebraic* content. This was unknown to Euclid, because the Greeks avoided numbers in geometry, so algebra was not even contemplated. It came to light only around 1630, when Fermat and Descartes introduced numbers and equations. The middle of this chapter describes the relationship, discovered by Descartes, between straightedge and compass constructions and *constructible numbers*—those obtainable from rational numbers by the operations of $+$, $-$, $\cdot$, $\div$, and $\sqrt{\ }$.

Finally, we discuss Euclid's modern incarnation: the *Euclidean geometry* of vector spaces with an *inner product*. Vector spaces capture the *linearity* of Euclid's geometry, traceable back to the straightedge, while the inner product captures the concept of length compatible with the Pythagorean theorem. Perhaps Euclid's geometry is so durable because it fits into both the ancient and modern worlds. Its ancient basis in hand tools—straightedge and compass—is exactly equivalent to its modern basis in vector spaces and inner products.

5.1 Numbers and Geometry

In modern mathematics, elementary geometry is *arithmetized* by reducing it to linear algebra over the real numbers. We will see how this is done in sections 5.7 and 5.8. Advanced geometry is arithmetized, too, by means of algebraic or differentiable functions of real or complex numbers. Yet somehow it is still easier for most humans to approach geometry visually, so visual objects re-emerge from the primordial soup of numbers and we find ways to simulate visual operations by operations on numbers. We represent points as ordered pairs (x, y) of real numbers, lines by linear equations $ax + by + c = 0$, circles by quadratic equations $(x - a)^2 + (y - b)^2 = r^2$; we find their intersection points by solving pairs of equations; we move objects by linear transformations of the set $\mathbb{R}^2$ of pairs (x, y); and so on. In this way we can model Euclid's geometry by higher-order concepts in the world of numbers.

This process has been recapitulated, in the last few decades, in the evolution of computers. Numbers are of course the native language of computers and, in their early decades of existence, computers were used mainly for processing numerical data. Then, in the 1970s, we saw the first crude printouts of images, typically made by assembling large arrays of symbols in a pattern printed on a long strip of paper. In the 1980s we started to program images, pixel by pixel, to be shown on computer screens. At the resolution then available (320×200) the results were usually hideous, as can be confirmed by looking at certain mathematics books of the period. When graphics commands were added to programming languages, it was a serious problem to program the best-looking "straight line" between two points. Any sloping line looked more or less like a staircase.

But resolution gradually improved and, by the 1990s, lines looked straight, curves looked smooth, and most pictures could be reproduced quite faithfully. This opened the floodgates of visual computing, leading

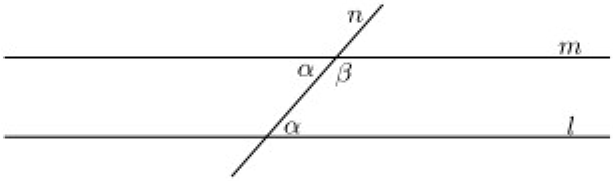

Figure 5.1: Angles involved in the parallel axiom.

to the world today in which users (particularly of phones and tablets) interact mainly with pictures on their screens: tapping them, translating and rotating them, magnifying them, and flipping them over by direct touch. It seems as though we *want* computers to be geometric, even if they have to be built on numbers, so programmers have to develop high-level programming concepts to model geometric operations.

In the present chapter we will study the interplay between numbers and geometry. There are reasons for doing geometry *without* a general concept of number, as we will see, and indeed Euclid did remarkable things without it. In the next two sections we review some of the big successes of his geometry: the theory of angles and the theory of area. But on balance geometry is easier with a suitable concept of number, and in the rest of the chapter we develop geometry on that basis.

5.2 Euclid's Theory of Angles

We are used to measuring angles by numbers: initially by degrees and at a higher level by radians, which involve the specific number π. But Euclid got by with the *right angle* as the unit of angle measure, and the concept of angle *equality*. His main conceptual tools for determining equality of angles were *congruence of triangles* and the *parallel axiom*. Indeed, the parallel axiom is the characteristic feature of Euclidean geometry, so we begin there. For convenience we use a slight variant of the parallel axiom, but it is equivalent to Euclid's.

Parallel Axiom. If lines l and m are parallel (that is, do not meet), and line n crosses them, then the angles α and β made by n with l and m, respectively, on the same side of n, have sum $\alpha + \beta$ equal to two right angles (figure 5.1).

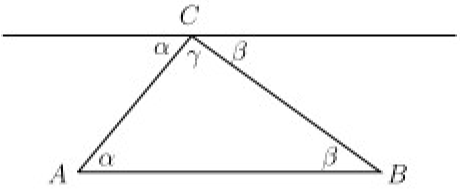

Figure 5.2: Angle sum of a triangle.

It follows that the angle adjacent to β is also α, since its sum with β is a straight angle, which equals two right angles. This immediately gives:

Angle sum of a triangle. *The angles α, β, γ of any triangle have sum $\alpha + \beta + \gamma$ equal to two right angles.*

Proof. Given a triangle ABC, with angles α, β, γ at the vertices A, B, C, respectively, consider the parallel to AB through the vertex C (figure 5.2).

Then it follows from the parallel axiom that angles α and β are adjacent to angle γ at C. Together, the angles at C below the parallel make a straight angle, so

$$\alpha + \beta + \gamma = \text{two right angles}. \qquad \square$$

Now we come to the use of congruence in establishing equality of angles. The relevant congruence axiom is the one today called SSS (for "side side side"): *if triangles ABC and $A'B'C'$ have corresponding sides equal then their corresponding angles are equal.* A famous consequence of SSS is a theorem about *isosceles* triangles (triangles with two equal sides).

Isosceles triangle theorem. *If ABC is a triangle with $AB = AC$, then the angle at B equals the angle at C.*

Proof. A stunning proof of this theorem (different from Euclid's) was given by Pappus, a Greek mathematician who lived some centuries later than Euclid.

Pappus noticed that triangle ABC is congruent to triangle ACB (yes, the same triangle, but "flipped," as it were) by SSS, because the

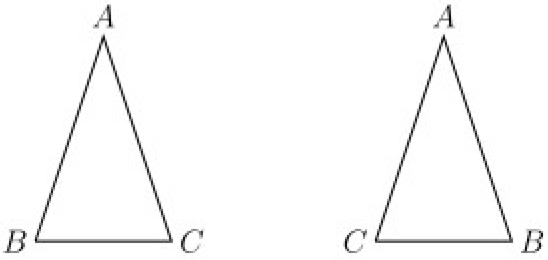

Figure 5.3: An isosceles triangle is congruent to itself.

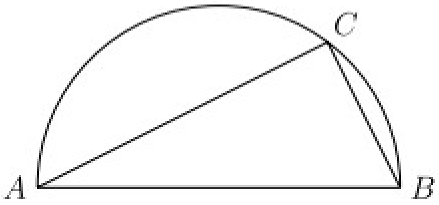

Figure 5.4: Angle in a semicircle.

corresponding sides

$$AB \text{ and } AC, \quad AC \text{ and } AB, \quad BC \text{ and } CB$$

are equal (see figure 5.3).

So the corresponding angles, at B and C, are also equal. □

Now we combine these two theorems about angles to obtain:

Angle in a semicircle. *If AB is the diameter of a circle, and C is another point on the circle, then the angle at C in triangle ABC is a right angle (figure 5.4).*

Proof. Let O be the center of the circle, and draw the line segment OC. This creates two isosceles triangles, OAC and OBC, because $OA = OB = OC$ (as radii of the circle). Then it follows from the isosceles triangle theorem that we have equal angles as shown in figure 5.5.

Also, since the angle sum of the triangle ABC is two right angles, we have

$$\alpha + (\alpha + \beta) + \beta = \text{two right angles.}$$

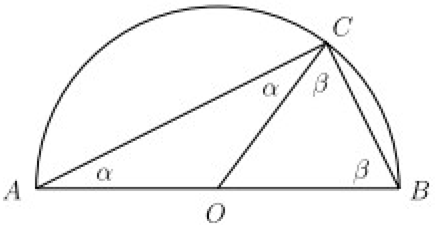

Figure 5.5: Isosceles triangles in a semicircle.

Therefore,

$$\alpha + \beta = \text{angle at C} = \text{right angle}. \qquad \square$$

5.3 Euclid's Theory of Area

According to legend, around 500 BCE the Pythagoreans discovered the irrationality of $\sqrt{2}$, or in their terms the *incommensurability* of the side and diagonal of the square. That is, there is no common unit of measure, u, such that the side and diagonal of the square are both integer multiples of u. Thus, the concept of positive integer—the *only* number concept the Pythagoreans had—is *inadequate* for describing all the lengths occurring in geometry. This momentous discovery led to a distinctive feature of Greek mathematics: the concept of *length* takes the place of number, but the arithmetic of lengths is quite limited. Lengths can be added and subtracted, but not multiplied. This means that area and volume have to be treated as separate kinds of magnitude, with even less capacity for addition and subtraction. In particular, the Greek concept of *equality* for areas and volumes is quite complicated.

Nevertheless, the Greeks were able to develop all the theory of area and volume needed for elementary mathematics. Here is how the theory of area gets off the ground.

Given lengths a and b, we modern mathematicians would like to say that the "product of a and b" is the area of the rectangle with adjacent sides a and b, which we may call the *rectangle of* a and b.

But what is area? It is certainly not a length, so from the Greek point of view there is no such thing as the area of the rectangle, other than the rectangle *itself* (figure 5.6). However there is a notion of *equality* for

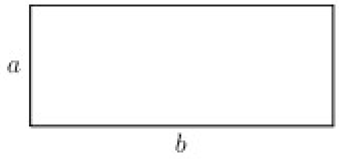

Figure 5.6: The rectangle of a and b.

rectangles which turns out to agree with the modern notion of equality of area, not only for rectangles but for all polygons. This notion of equality is based on the following principles, which are called "common notions" in Book I of Euclid's *Elements*.

1. Things which are equal to the same thing are also equal to each other.
2. If equals be added to equals, the wholes are equal.
3. If equals be subtracted from equals, the remainders are equal.
4. Things which coincide with one another are equal to one another.
5. The whole is greater than the part.

Notions 1, 2, 3, and 4 say essentially that objects are "equal" if one can be converted to the other by finitely often adding or subtracting identical ("coinciding") pieces. We already used these notions to prove the Pythagorean theorem in section 1.4. Notion 5 is not needed at this stage, because it turns out that Notions 1, 2, 3, and 4 suffice to prove that any polygons of equal area (in the modern sense) are "equal" in Euclid's sense.

The fact that "equal in area" is the same as "equal in Euclid's sense" (for polygons) is an elementary theorem. It was discovered in the nineteenth century by F. Bolyai and Gerwien, and is rather tedious to prove. Here we are content to show how the idea applies to the most important areas in elementary geometry—those of parallelograms and triangles. From now on we will say "equal in area" rather than "equal in Euclid's sense."

First, we see that the rectangle R of a and b is equal in area to any parallelogram P of height a and base b, because we can convert R to P by adding a triangle T to one side of R and then subtracting an identical triangle from the other side of the resulting shape (figure 5.7).

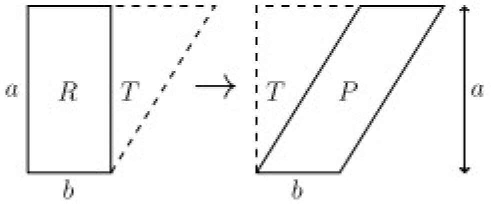

Figure 5.7: Converting a rectangle to a parallelogram.

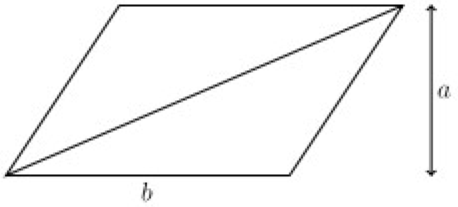

Figure 5.8: Making a parallelogram from two copies of a triangle.

Thus any parallelogram is equal in area to a rectangle with the same base and height. It follows that a triangle with height a and base b is equal in area to the rectangle with base b and half the height, $a/2$, because two copies of the triangle make a parallelogram of base b and height a (figure 5.8).

Since rectangles of equal area are actually "equal" in Euclid's sense we can *define* the product ab of lengths a and b to be the rectangle of a and b, and call products "equal" if the corresponding rectangles are "equal" in Euclid's sense. Then if $ab = cd$, we can *prove* this fact by converting the rectangle of c and d to the rectangle of a and b by adding and subtracting identical pieces. Thus, $ab = cd$ is actually *equivalent* to "equality" (in Euclid's sense) of the rectangle of a and b with the rectangle of c and d.

Even without knowing this general fact (which depends on the theorem of Bolyai and Gerwein) the Greeks could have proved "equality" of some interesting irrational rectangles, though it is not known whether they ever did so.

Geometric Proof that $\sqrt{2} \cdot \sqrt{3} = \sqrt{6}$

One of the supposed advantages of the theory of real numbers, introduced by Dedekind (1872), is that it permits rigorous proofs of

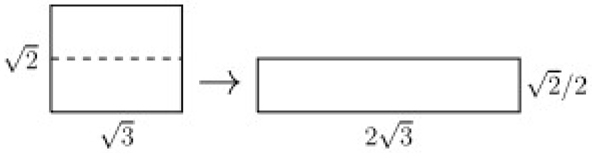

Figure 5.9: Converting the $\sqrt{2}$ by $\sqrt{3}$ rectangle to half height.

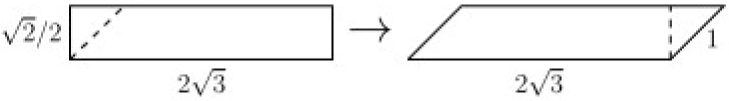

Figure 5.10: Converting rectangle to parallelogram.

results such as $\sqrt{2} \cdot \sqrt{3} = \sqrt{6}$. Indeed, Dedekind speculated that, with his definition of real number,

> we arrive at real proofs of theorems (as, e.g., $\sqrt{2} \cdot \sqrt{3} = \sqrt{6}$) that have never been established before.
>
> Dedekind (1901), p. 22

It may be true that $\sqrt{2} \cdot \sqrt{3} = \sqrt{6}$ had never really been proved before, but there was nothing to stop the Greeks from proving an equivalent proposition. Gardiner (2002), pp. 181–183 has pointed out that we can interpret and prove this equation quite easily in terms the Greeks would have accepted. Here is one such proof (a variation on Gardiner's), which is surely elementary.

By the Pythagorean theorem, $\sqrt{2}$ is the diagonal of the unit square and $\sqrt{3}$ is a side of the right-angled triangle with hypotenuse 2 and other side 1. Thus we can interpret $\sqrt{2}$ and $\sqrt{3}$ as lengths, and it is meaningful to speak of the rectangle of $\sqrt{2}$ and $\sqrt{3}$. We now transform this rectangle, by adding and subtracting equal pieces, into a rectangle of base 1.

First, cut the rectangle in two equal parts by a line parallel to the base $\sqrt{3}$, and then combine these two parts into a rectangle of height $\sqrt{2}/2$ and base $2\sqrt{3}$ (figure 5.9).

These rectangles are "equal" in Euclid's sense.

Next, we convert the new rectangle into a parallelogram by cutting off a right-angled triangle with equal sides $\sqrt{2}/2$ (and hence hypotenuse 1 by the Pythagorean theorem) from the left end and attaching it to the right (figure 5.10).

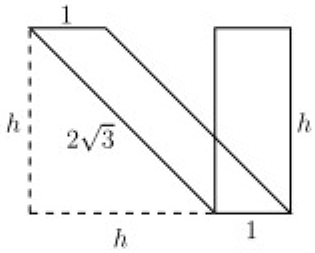

Figure 5.11: Converting parallelogram to rectangle with base 1.

The result is a parallelogram of the same width but sloping sides (at angle 45°) of length 1, and of course the same area again.

Finally, viewing the side 1 as the base of the parallelogram, we convert it to a rectangle with the same base and height, and hence the same area, by adding and subtracting a triangle (figure 5.11). It remains to find the height h of the rectangle.

We notice from figure 5.11 that h is the side of the isosceles right-angled triangle with hypotenuse $2\sqrt{3}$. Hence, by the Pythagorean theorem again,

$$h^2 + h^2 = (2\sqrt{3})^2 = 4 \times 3 = 12, \quad \text{so} \quad h^2 = 6.$$

This completes the proof that the rectangle with sides $\sqrt{2}$ and $\sqrt{3}$ is equal in area to the rectangle with sides $\sqrt{6}$ and 1. Hence (in modern terms) $\sqrt{2} \cdot \sqrt{3} = \sqrt{6}$.

The Concept of Volume

Euclid had a theory of volume that begins in the same way as his theory of area. The basic solid object is the *box* of a, b, and c; that is, with height a and base the rectangle of b and c, and all faces rectangular. "Equality" is defined by adding and subtracting identical pieces, and one finds that a *parallelepiped*[1] (a "squashed box" whose faces are parallelograms) is "equal" to the box with the same height, width, and depth (figure 5.12).

Next, by cutting a parallelepiped in half one finds that a *prism* is "equal" to the box with the same base but half the height. But that is

---

[1] This word is often misunderstood, misspelled, and mispronounced. It helps to read its parts as parallel-epi-ped, literally "parallel upon the foot," meaning that the top is parallel to the bottom, no matter which way is up.

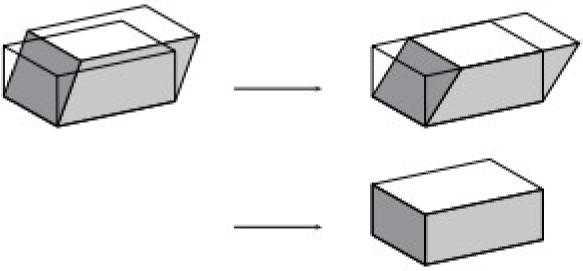

Figure 5.12: Transforming a squashed box to a box by adding and subtracting.

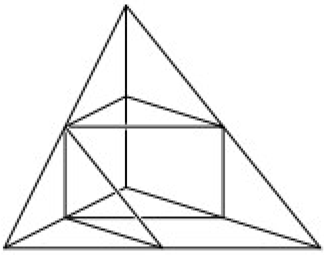

Figure 5.13: Two prisms in the tetrahedron.

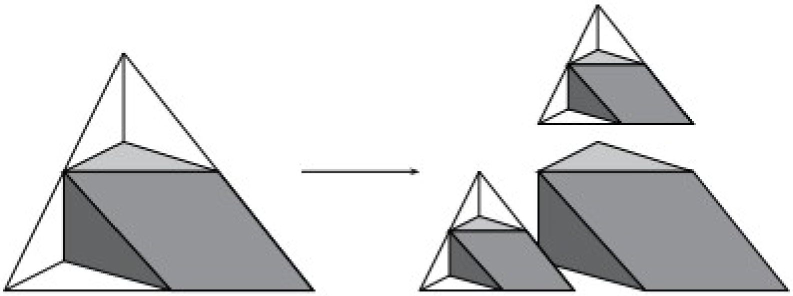

Figure 5.14: Continuing the dissection of the tetrahedron.

as far as one can go using finite numbers of pieces. In the case of the *tetrahedron*, Euclid was able to find an "equal" box only by cutting the tetrahedron into an *infinite* number of prisms. Figure 5.13 shows the first two prisms inside the tetrahedron, and figure 5.14 shows how to obtain further prisms, inside the tetrahedra that remain after the first two prisms are removed.

Much later, Dehn (1900) showed that the infinity is unavoidable: it is not possible to convert a regular tetrahedron to a cube by adding and subtracting finitely many pieces. This surprising discovery shows that volume is a deeper concept than area. If we suppose that volume belongs to elementary mathematics (as we presumably do), then we must accept that infinite processes have a place in elementary mathematics too. We pursue this train of thought further in the next chapter.

5.4 Straightedge and Compass Constructions

Many of the propositions in Euclid's *Elements* are *constructions*; that is, claims that certain figures in the plane can be constructed by drawing straight lines and circles. These constructions rest upon the ability to do two things that Euclid includes in his "postulates" (which we call axioms):

1. To draw a straight line from a given point to any other given point.
2. To draw a circle with given center and radius.

(Euclid actually splits the first axiom into two—drawing the line *segment* between given points and extending the segment arbitrarily far—because he does not admit infinite lines.) We now call the instruments for drawing lines and circles the "straightedge" and "compass," respectively,[2] so Euclid's constructions are called *straightedge and compass constructions*.

Euclid's very first proposition is a straightedge and compass construction: *drawing an equilateral triangle whose base is a given line segment* AB. It nicely illustrates how the compass is not only an instrument for drawing circles, but also for "storing" and "copying" lengths, because it allows a length to be carried from one place to another.

The third vertex C of the triangle is found at the intersection of the circles with centers A and B, respectively, and radius AB (figure 5.15). The triangle is then completed by drawing the line segments from A to C and from B to C.

---

[2] The straightedge is often called a ruler, but this wrongly suggests that there are marks on its edge that could be used for measurement. The compass used to be called a "pair of compasses." This term is falling into disuse, but I mention it because you may still see it in older books.

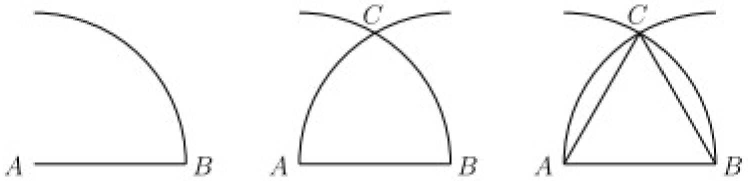

Figure 5.15: Constructing the equilateral triangle.

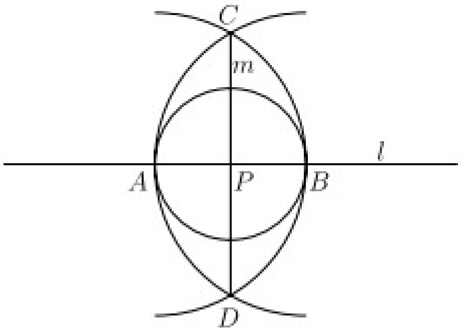

Figure 5.16: Constructing a perpendicular.

To prove that the construction is correct we observe that

$$\begin{aligned} & AC = AB \quad \text{because both are radii of the first circle,} \\ & BC = AB \quad \text{because both are radii of the second circle,} \\ \text{so} \quad & AB = AC = BC, \end{aligned}$$

because "things equal to the same thing are equal to one another."

Many other constructions in elementary geometry are variations on this one.

For example, the other intersection D of the two circles above gives a line CD *perpendicular* to AB and passing through its midpoint P. Conversely, by drawing a circle centered on an arbitrary point P on a line l we can make P the midpoint of a segment AB, and hence construct a line m perpendicular to l through P (figure 5.16).

Then, by constructing a perpendicular to m, we get a *parallel* n to the original line l. Parallels are a fundamental concept of Euclidean geometry, and they are the key to many constructions, because of the following theorem, which refers to figure 5.17.

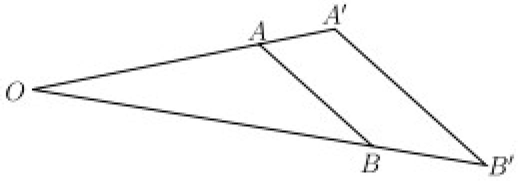

Figure 5.17: Setting of Thales' theorem.

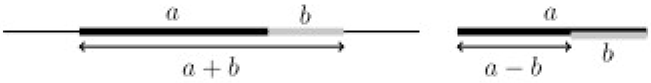

Figure 5.18: Forming the sum and difference of lengths.

Theorem of Thales. *If OAB and $OA'B'$ are triangles such that OAA' and OBB' are straight lines and AB is parallel to $A'B'$, then*

$$OA/OA' = OB/OB'.$$

Euclid's proof of this theorem is quite subtle, because his avoidance of numbers makes it hard to interpret the ratios OA/OA' and OB/OB'. When we accept that lengths are numbers we can argue much more simply (see section 5.7). This paves the way for straightedge and compass constructions that simulate all the arithmetic operations $+, -, \cdot, \div$ on lengths, as well as the $\sqrt{}$ operation. We carry out the most interesting parts of this program in the next section. But first we dispose of the $+$ and $-$ operations, which are simple even from Euclid's point of view and do not involve the theorem of Thales.

Given line segments a and b, we form $a + b$ by first extending the line segment a sufficiently far, then copying the line segment b with the compass and placing it alongside a in the same line. Similarly, if b is no greater than a, we form $a - b$ by carrying b to the interior of a with one end of b at the end of a (figure 5.18).

5.5 Geometric Realization of Algebraic Operations

As we saw at the end of the previous section, it is easy to obtain the sum and difference of lengths by constructions within the line. Product and quotient are also easy to obtain, but the construction makes use of the

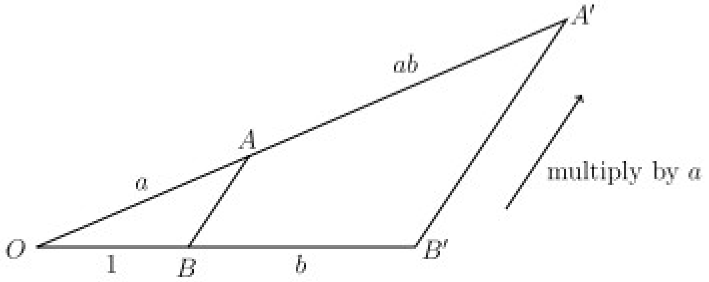

Figure 5.19: Constructing the product of lengths.

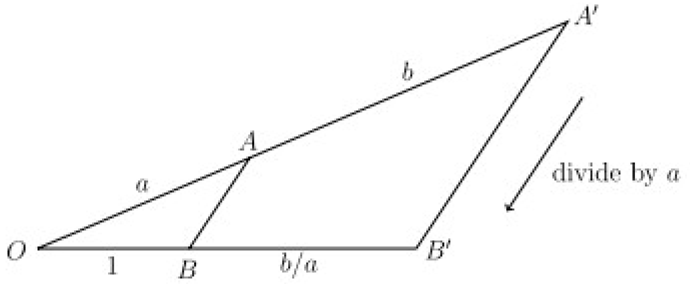

Figure 5.20: Constructing the quotient of lengths.

plane, and parallel lines. We also need to fix a *unit length*. But then, if we are given a length a, we can multiply any length b by a using the construction shown in figure 5.19.

The construction uses two lines through O. On one of them we mark the unit length $1 = OB$; on the other, the length $a = OA$. Then on the first line we add the length $b = BB'$. Finally, we draw AB and its parallel $A'B'$ through B'. By the theorem of Thales it follows that $AA' = ab$.

In effect, the parallels achieve "magnification by a," mapping the segments of length 1, b onto segments of length a, ab. The reverse direction gives "division by a," and hence we can obtain b/a for any lengths a, b as shown in figure 5.20.

Thus we now have geometric realizations of the operations $+, -, \cdot, \div$. To realize the operation $\sqrt{}$ is also surprisingly easy, but first we need the following consequence of the theorem of Thales.

Proportionality of Similar Triangles. *If ABC and $A'B'C'$ are triangles whose corresponding angles are equal (that is, angle at A equals angle*

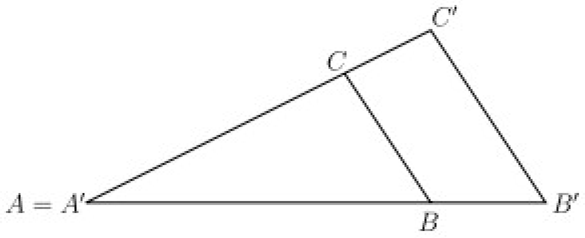

Figure 5.21: Similar triangles.

at A' and so on) then their corresponding sides are proportional. That is

$$\frac{AB}{A'B'} = \frac{BC}{B'C'} = \frac{CA}{C'A'}.$$

Proof. Move the triangle $A'B'C'$ to the position where $A = A'$, A, B, B' are in the same line, and A, C, C' are in the same line. We assume A, C, C' are in that order, in which case we have the situation shown in figure 5.21. (The argument is similar if the order is A, C', C.)

Since the angles at C and C' are equal, the lines BC and $B'C'$ are parallel. Then it follows from the theorem of Thales that the upper and lower sides are divided proportionally; that is, $AB/A'B' = AC/A'C'$. Similarly, by moving the triangles so that B coincides with B', we find that $BC/B'C' = BA/B'A' = AB/A'B'$. So in fact all pairs of corresponding sides are proportional. □

Now to construct $\sqrt{l}$ for any length l we make the construction shown in figure 5.22. This is Euclid's construction in his Book VI, Proposition 13.

As we saw in section 5.2, the angles α and β at A and B, respectively, have sum $\alpha + \beta$ equal to a right angle. It follows, since the angle sum of each triangle is two right angles, that the angles at C are also α and β as shown. Thus triangles ADC and CDB are similar. Comparing corresponding sides we obtain the equal ratios

$$1/h = h/l,$$

from which it follows that

$$h^2 = l, \quad \text{and therefore} \quad h = \sqrt{l}.$$

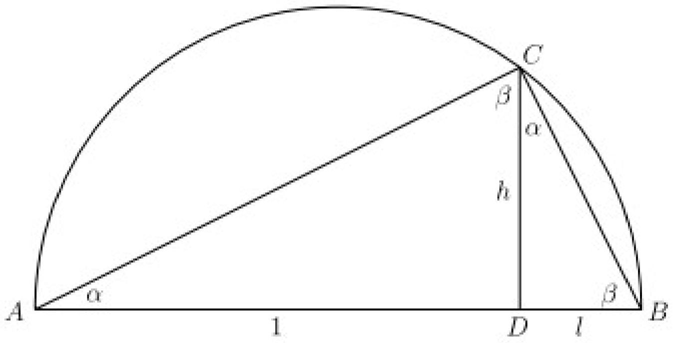

Figure 5.22: Constructing the square root of a length.

Moreover, we can *construct* $\sqrt{l}$ in the following steps.

1. Add l to 1 in the same line to form the line segment AB.
2. Bisect AB to find the center of the circle with diameter AB.
3. Draw this circle.
4. Construct the perpendicular to AB at the point D where the segments 1 and l meet.
5. Find the intersection C of this perpendicular with the circle of diameter AB and draw CD.

5.6 Algebraic Realization of Geometric Constructions

In the previous section we saw that straightedge and compass constructions include the algebraic operations of $+$, $-$, $\cdot$, $\div$, and $\sqrt{}$. In this section we will show that, when straightedge and compass operations are interpreted in the plane $\mathbb{R}^2$, *all* constructible lengths are obtainable from the unit length by the above operations. Thus we have an equivalence between geometric and algebraic concepts, and with it the opportunity to prove existence or nonexistence of geometric constructions by algebra. We will give an example of existence at the end of this section, and an example of nonexistence in section 5.9.

We begin by using coordinates to interpret the two basic constructions: drawing the line through two given points, and drawing the circle with given center and radius.

y coordinates of the intersection come from the solutions for x and the first equation, again using $+, -, \cdot, \div$.

- Given two circles $(x-a_1)^2+(y-b_1)^2=r_1^2$ and $(x-a_2)^2+(y-b_2)^2=r_2^2$, we expand these two equations as

  $$x^2-2a_1x+a_1^2+y^2-2b_1y+b_1^2=r_1^2,$$
  $$x^2-2a_2x+a_2^2+y^2-2b_2y+b_2^2=r_2^2.$$

  Subtraction cancels the x^2 and y^2 terms, leaving a linear equation whose common solutions with either of the circle equations can be found as in the previous case.

To sum up: the coordinates of all new points, and hence the coefficients in the equations of all new lines and circles, are obtainable from the coordinates of the initially given points by the operations $+, -, \cdot, \div$, and $\sqrt{\ }$. Therefore, the coordinates of all points constructible by straightedge and compass are obtainable from 1 by these operations. Conversely, all points whose coordinates are numbers obtainable from 1 by the operations $+, -, \cdot, \div$, and $\sqrt{\ }$ (which we may call *constructible numbers*) are constructible by straightedge and compass.

Now here is the promised example: using algebra to prove constructibility.

The Regular Pentagon

Figure 5.23 shows the regular pentagon with sides of length 1 and a diagonal whose length x is sought. The other two diagonals are drawn to create some similar triangles. The symmetry of the regular pentagon ensures that each diagonal is parallel to the opposite side, and the various parallels imply that the triangles ABC, $A'BC$, and $A'B'C'$ have the equal angles α shown, and hence also equal angles β.

Thus $A'BC$ is similar to ABC and, since they have the common side BC, they are actually *congruent*. This gives the equal sides of length 1 shown in figure 5.24, hence also the sides of length $x-1$, since all diagonals have length x.

Then similarity of triangles ABC and $A'B'C'$ gives

$$\frac{1}{x}=\frac{x-1}{1}$$

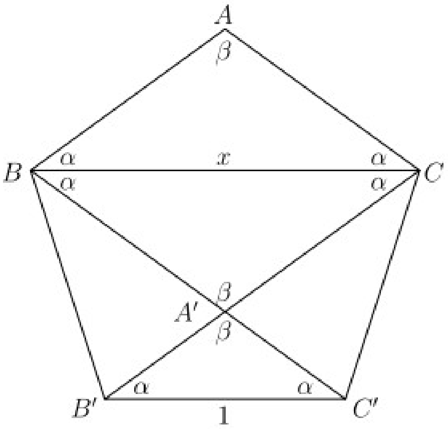

Figure 5.23: Angles in the regular pentagon.

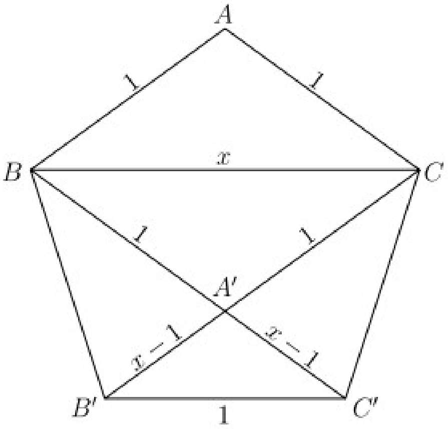

Figure 5.24: Lengths in the regular pentagon.

from the proportionality of corresponding sides. This is the quadratic equation $x^2 - x - 1 = 0$, which has the solutions $x = \frac{1 \pm \sqrt{5}}{2}$. The positive member of this pair is the length of the pentagon diagonal. It is a constructible number, so we can construct the diagonal by straightedge and compass. It is then easy to construct the triangle ABC, and to join a series of such triangles together to form the regular pentagon.

5- T 2 <73

among the next simplest, with constant (but negative) curvature at all points. In the modern geometry of curved spaces, Euclidean spaces have a special place as *tangent spaces*. A curved manifold has a tangent space at each point, and one often works in the tangent space to take advantage of its simpler structure (particularly, its nature as a vector space).

It is all very well to base geometry on the theory of real numbers, but how well do we understand the real numbers? What is *their* foundation? Hilbert (1899) raised this question, and he had an interesting answer: the real numbers can be based on geometry! More precisely, they can be based on a "completed" version of Euclid's geometry. Hilbert embarked on the project of completing Euclid's axioms in the early 1890s, first with the aim of filling in some missing steps in Euclid's proofs. As the project developed, he noticed that addition and multiplication arise from his axioms in a quite unexpected way, so that the field concept can be given a completely geometric foundation. See section 5.11. Then, by adding an axiom guaranteeing that the line has no gaps, he was able to recover a complete "number line" with the usual properties of $\mathbb{R}$.

*Non-Euclidean Geometry

In the 1820s, Janos Bolyai[5] and Nikolai Lobachevsky independently developed a rival geometry to Euclid's: a *non*-Euclidean geometry that satisfied all of Euclid's axioms except the parallel axiom. The parallel axiom has a different character from the other axioms, which describe the outcome of finite constructions or "experiments" one can imagine carrying out:

1. Given two points, draw the line segment between them.
2. Extend a line segment for any given distance.
3. Draw a circle with given center and radius.
4. Any two right angles are equal (that is, one can be moved to coincide with the other).

The parallel axiom, on the other hand, requires an experiment that involves an indefinite wait:

---

[5] Son of the Bolyai in the Bolyai-Gerwien theorem.

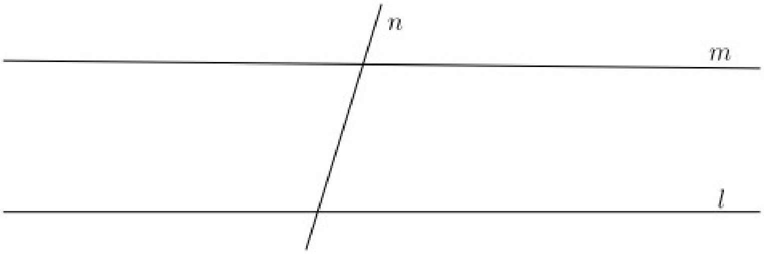

Figure 5.31: Two lines that are supposed to meet.

5. Given two lines l and m, crossed by another line n making interior angles with l and m together less than two right angles, the lines l and m will meet, *if produced indefinitely* (figure 5.31).

Since the time of Euclid, mathematicians have been unhappy with the parallel axiom, and have tried to prove it from the other, more constructive, axioms. The most determined attempt was made by Saccheri (1733), who got as far as showing that, if non-diverging lines l and m did *not* meet, they would have a common perpendicular at infinity. This, Saccheri thought, was "repugnant to the nature of straight lines." But it was not a contradiction, and in fact there is a geometry in which lines behave in precisely this fashion.

Bolyai and Lobachevsky worked out a large and coherent body of theorems that follow from Euclid's axioms 1 to 4 together with the axiom:

5′. There exist two lines l and m, which do not meet, although they are crossed by another line n making interior angles with l and m together less than two right angles.

Their results were eventually published in Lobachevsky (1829) and Bolyai (1832) (the latter an appendix to a book by Bolyai's father). They found no contradiction arising from this set of axioms, and Beltrami (1868) showed that no contradiction exists, because axioms 1, 2, 3, 4, and 5′ are satisfied under a suitable interpretation of the words "point," "line," and "angle." (We sketch one such interpretation below.) Thus Euclid's geometry had a rival, and deciding how to interpret the terms "point," "line," "distance," and "angle" became an issue.

As we have seen, Euclid's axioms had a ready-made interpretation in the coordinate geometry of Descartes: a "point" is an ordered pair (x, y) of real numbers, a "line" consists of the points satisfying an equation $ax + by + c = 0$, and the "distance" between (x_1, y_1) and (x_2, y_2) equals $\sqrt{(x_2 - x_1)^2 + (y_2 - y_2)^2}$.

For Bolyai's and Lobachevsky's axioms, Beltrami found several elegant interpretations, admittedly with a somewhat complicated concept of "distance." The simplest is probably the *half-plane model*, in which:

- "points" are points of the upper half-plane; that is, pairs (x, y) with $y > 0$,
- "lines" are the open semicircles in the upper half-plane with their centers on the x-axis, and the open half-lines $\{(x, y) : x = a, y > 0\}$,
- the "distance" between "points" P and Q is the integral of $\sqrt{dx^2 + dy^2}/y$ over the "line" connecting P and Q.

It turns out that "angle" in this model is just the ordinary angle between curves; that is, the angle between their tangents. This leads to some beautiful pictures of non-Euclidean geometric configurations, such as the one in figure 5.32. It shows a tiling of the half-plane by triangles which are "congruent" in the sense of non-Euclidean distance. In particular, they each have angles $\pi/2$, $\pi/3$, $\pi/7$. Knowing that they are congruent one can get a sense of non-Euclidean distance. One can see that the x-axis is infinitely far away—which explains why it is not included in the model—and perhaps also see that a "line" is the shortest path joining its endpoints, if one estimates distance by counting the number of triangles along a path.

It is also clear that the parallel axiom fails in the model. Take for example the "line" that goes straight up the center of the picture and the point on the far left with seven "lines" passing through it. Several of the latter "lines" do not meet the center line.

*Vector Space Geometry

Grassmann (1861), the *Lehrbuch der Arithmetik* mentioned in section 1.9, was not Grassmann's only great contribution to the

Numbers and Geometry

Now let us return to the axioms of Hilbert (1899), and what they tell us about the relationship between numbers and geometry. Hilbert's axioms probably capture Euclid's concept of the line (with the finer structure explored in Book V of the *Elements*). So, given the Descartes "model" $\mathbb{R}^2$ of Euclid's axioms, Hilbert has shown Euclidean geometry to be essentially *equivalent* to the algebra of $\mathbb{R}$. However, algebraists and logicians now prefer not to use the full set $\mathbb{R}$ in geometry. They point out that the set of constructible numbers suffices, because Euclid's geometry "sees" only the points arising from straightedge and compass constructions. Thus one can get by with an algebraically defined set of points, which is only a "potential" infinity, in contrast to the "actual" infinity $\mathbb{R}$. Logicians also prefer the theory of constructible numbers because its "consistency strength" is less than that of the theory of $\mathbb{R}$.

That is, it is easier to prove the consistency of the theory of constructible numbers (and hence the consistency of Euclid's axioms) than it is to prove the consistency of the theory of $\mathbb{R}$ (and hence the consistency of Hilbert's axioms).

Geometry and "Reverse Mathematics"

In recent decades, mathematical logicians have developed a field called *reverse mathematics*, whose motivation was stated by Friedman (1975) as follows:

> When the theorem is proved from the right axioms, the axioms can be proved from the theorem.

As logicians understand it, reverse mathematics is a technical field, concerned mainly with theorems about the real numbers (see section 9.9). However, if we understand reverse mathematics more broadly as the search for the "right axioms," then reverse mathematics began with Euclid.

He saw that the parallel axiom is the right axiom to prove the Pythagorean theorem, and perhaps the reverse—that the Pythagorean theorem proves the parallel axiom (given his other axioms). The same is true of many other theorems of Euclidean geometry, such as the theorem of Thales and the theorem that the angle sum of a triangle is π. All of these theorems are equivalent to the parallel axiom, so it is the "right axiom" to prove them.

To formalize this and other investigations in reverse mathematics we choose a *base theory* containing the most basic and obvious assumptions about some area of mathematics. It is to be expected that the base theory will fail to prove certain interesting but less obvious theorems. We then seek the "right" axiom or axioms to prove these theorems, judging an axiom to be "right" if it implies the theorem, and conversely, using only assumptions from the base theory.

Euclid began with a base theory now known as *neutral geometry*. It contains basic assumptions about points, lines, and congruence of triangles but *not* the parallel axiom. He proved as many theorems as he could before introducing the parallel axiom—only when it was needed to prove theorems about the area of parallelograms and ultimately the Pythagorean theorem. He also needed the parallel axiom to prove the theorem of Thales and that the angle sum of a triangle is π. We now know, conversely, that all of these theorems imply the parallel axiom in neutral geometry, so the latter is the "right" axiom to prove them.

Neutral geometry is also a base theory for *non*-Euclidean geometry, because the latter is obtained by adding to neutral geometry the "non-Euclidean parallel axiom" stating that there is more than one parallel to a given line through a given point.

Grassmann's theory of real vector spaces, as we have seen, can also be taken as a base theory for Euclidean geometry. It is quite different from the base theory of neutral geometry because the Euclidean parallel axiom *holds* in real vector spaces, and so does the theorem of Thales. Nevertheless, this new base theory is not strong enough to prove the Pythagorean theorem, or indeed to say anything about angles. Relative to the theory of real vector spaces, the "right" axiom to prove the Pythagorean theorem is existence of the inner product, because we can reverse the implication by using the Pythagorean theorem to define distance, hence angle and cosine, and then define the inner product by

$$\boldsymbol{u} \cdot \boldsymbol{v} = |\boldsymbol{u}| \cdot |\boldsymbol{v}| \cos \theta.$$

This raises the possibility of adding a different axiom to the theory of real vector spaces and obtaining a different kind of geometry, just as we obtain non-Euclidean geometry from neutral geometry by adding a different parallel axiom. Indeed we can, and simply by asserting the existence of a different kind of inner product. The inner product introduced by Grassmann is what we now call a *positive-definite* inner product, characterized by the property that $\boldsymbol{u} \cdot \boldsymbol{u} = 0$ only if $\boldsymbol{u}$ is the zero vector.

Non-positive-definite inner products also arise quite naturally. Probably the most famous is the one on the vector space $\mathbb{R}^4$ that defines the *Minkowski space* of Minkowski (1908). If we write the typical vector in $\mathbb{R}^4$ as $\boldsymbol{u} = (w, x, y, z)$ then the Minkowski inner product is defined by

$$\boldsymbol{u}_1 \cdot \boldsymbol{u}_2 = -w_1 w_2 + x_1 x_2 + y_1 y_2 + z_1 z_2.$$

In particular, the length $|\boldsymbol{u}|$ of a vector $\boldsymbol{u}$ in Minkowski space is given by

$$|\boldsymbol{u}|^2 = \boldsymbol{u} \cdot \boldsymbol{u} = -w^2 + x^2 + y^2 + z^2,$$

so $|\boldsymbol{u}|$ can certainly be zero when $\boldsymbol{u}$ is not the zero vector.

Minkowski space is famous as the geometric model of Einstein's *special relativity theory*. In this model, known as *flat spacetime*, x, y, and z are the coordinates of ordinary three-dimensional space and $w = ct$, where t is the time coordinate and c is the speed of light. As Minkowski (1908) said:

> The views of space and time which I wish to lay before you have sprung from the soil of experimental physics, and therein lies their strength. They are radical. Henceforth space by itself, and time by itself, are doomed to fade away into mere shadows, and only a kind of union of the two will preserve an independent reality.

Undoubtedly, relativity theory put non-positive-definite inner products on the map, making them as real and important as the ancient concept of distance. But in fact such inner products had already been considered by mathematicians, and one of them is involved in a model of non-Euclidean geometry discovered by Poincaré (1881)—the so-called *hyperboloid model*.

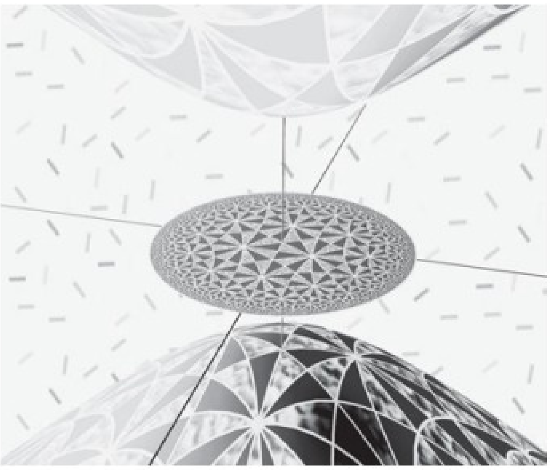

Figure 5.34: Triangle tessellation of the hyperboloid model.

To see where the hyperboloid comes from, consider the three-dimensional Minkowski space of vectors $\boldsymbol{u} = (w, x, y)$ with one time coordinate w and two space coordinates x, y. In this space, where $|\boldsymbol{u}|^2 = -w^2 + x^2 + y^2$, we consider the "sphere of imaginary radius"

$$\{\boldsymbol{u} : |\boldsymbol{u}| = \sqrt{-1}\} = \{(w, x, y) : -w^2 + x^2 + y^2 = -1\}.$$

This "sphere"[8] consists of the points (w, x, y) in $\mathbb{R}^3$ such that

$$w^2 - x^2 - y^2 = 1,$$

so it is actually a hyperboloid; namely, the surface obtained by rotating the hyperbola $w^2 - y^2 = 1$ in the (w, y)-plane about the w axis. If we take "distance" on either sheet of the hyperboloid to be the Minkowski distance, it turns out to be a model of the non-Euclidean plane. As with the other models of the non-Euclidean plane, calculating distance is a little troublesome so I omit the details. Instead, I offer figure 5.34—a black-and-white version of a picture due to Konrad Polthier of the Freie Universität, Berlin—which shows what the triangle tessellation of

---

[8] Long before the development of Minkowski space, or even the development of non-Euclidean geometry, Lambert (1766) speculated about the geometry of a "sphere of imaginary radius." In particular, he guessed that the angle sum of a triangle would be less than π on such a sphere—which is essentially the non-Euclidean parallel axiom.

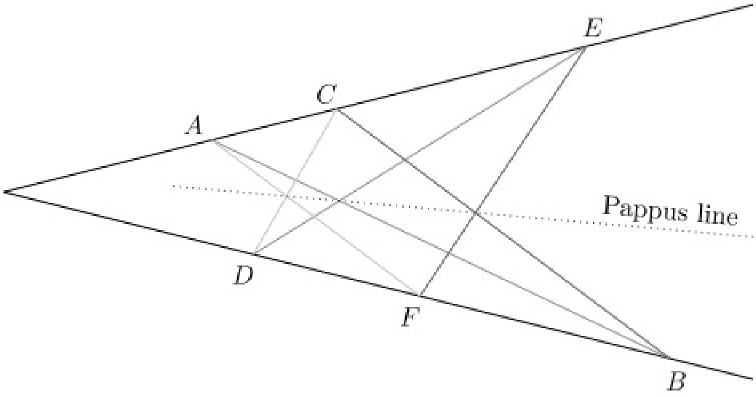

Figure 5.35: The Pappus configuration.

figure 5.32 looks like in the hyperboloid model. (It also relates the hyperboloid model to another model—the *conformal disk* model—which is a kind of intermediary between the hyperboloid model and the half-plane model shown in figure 5.32.)

This elegant relationship between Minkowski space and the non-Euclidean plane has been used for some textbook treatments of non-Euclidean geometry, such as Ryan (1986). Just as the positive-definite inner product is the "right axiom" to develop Euclidean geometry over the base theory of real vector spaces, the Minkowski inner product is the "right axiom" to develop non-Euclidean geometry.

*Projective Geometry

Another wonderfully "right" axiom is the theorem discovered by Pappus a few hundred years after Euclid. Pappus viewed his theorem as part of Euclidean geometry, but it does not really belong there. It is unlike typical Euclidean theorems in making no mention of length or angle, so its home should be a geometry that does not involve these concepts. The statement of the theorem is the following, which refers to the configuration shown in figure 5.35.

Theorem of Pappus. *If A, B, C, D, E, F are points of the plane lying alternately on two lines, then the intersections of the pairs of lines AB and DE, BC and EF, CD and FA, lie on a line.*

The Pappus theorem has a Euclidean *proof* using the concept of length, and also a coordinate proof using linear equations to define lines. But it seems to have no proof using only concepts "appropriate" to its statement: points, lines, and the membership of points in lines. The appropriate setting for the Pappus theorem is the *projective geometry* of the plane, a geometry which tries to capture the behavior of points and lines in a plane without regard to length or angle. In projective geometry, configurations of points and lines are considered the same if one can be projected onto the other. Projection can of course change lengths and angles, but the straightness of lines remains, as does the membership of points in lines.

If one seeks axioms for projective plane geometry, the following come easily to mind:

1. Any two points belong to a unique line.
2. Any two lines have a unique point in common.
3. There are four points, no three of which are in the same line.

The first axiom is also one of Euclid's. The second disagrees with Euclid in the case of parallel lines, but projective geometry demands it, because even parallel lines can be projected so that they meet—on the "horizon." The third axiom is there to ensure that we really have a "plane," and not merely a line. However, these simple axioms are very weak, and it can be shown that they do not suffice to prove the Pappus theorem. They do, however, form a natural base theory to which other axioms about points and lines can be added.

What are the "right axioms" to prove the Pappus theorem? The answer is no less than the Pappus theorem itself, thanks to what the Pappus theorem implies; namely, that the abstract plane of "points" and "lines" can be given *coordinates* which form a *field* as defined in section 4.3. Thus geometry springs fully armed from the Pappus theorem! The Pappus axiom (as we should now call it) is the right axiom to prove coordinatization by a field, because such a coordinatization allows us to prove the Pappus axiom. As remarked above, this follows by using linear equations to define lines. The field properties then enable us to find intersections of lines by solving linear equations, and to verify that points of intersection lie on a line.

The idea of reversing the coordinate approach to geometry began with von Staudt (1847), who used the Pappus axiom to define addition and multiplication of points on a line. Hilbert (1899) extended this idea to prove that the coordinates form a field, but he had to assume another projective axiom, the so-called *theorem of Desargues*, which was discovered around 1640. (Roughly speaking, the Pappus axiom easily implies that addition and multiplication are commutative, while the Desargues axiom easily implies that they are associative.) Quite remarkably, considering how long the Pappus and Desargues theorems had been around, Hessenberg (1905) discovered that the Pappus theorem implies the Desargues theorem. So the single Pappus axiom is in fact *equivalent* to coordinatization of the plane by a field.

This reversal of the Pappus theorem also tells us something remarkable about algebra: the nine field axioms follow from four geometric axioms—the three projective plane axioms plus Pappus!

in the geometric series $\frac{1}{2}+\frac{1}{2^2}+\frac{1}{2^3}+\cdots$ (see the example in the next subsection). But it is harder to prove it is valid to differentiate term by term and hence to prove that $\frac{d}{dx}\exp(x)=\exp(x)$. This involves the advanced version of the continuity concept called *uniform* continuity, which is normally reserved for advanced calculus courses.

The Irrationality of e

The series $e=1+\frac{1}{1!}+\frac{1}{2!}+\frac{1}{3!}+\frac{1}{4!}+\cdots$ is good for computation, because the terms decrease rapidly in size. The rapid decrease is also of theoretical value, because it gives a proof that e is irrational (due to Joseph Fourier around 1815).

Irrationality of ***e*****.** *The number e is not equal to m/n for any positive integers m and n.*

Proof. Suppose on the contrary that

$$\frac{m}{n}=1+\frac{1}{1!}+\frac{1}{2!}+\frac{1}{3!}+\cdots+\frac{1}{n!}+\cdots .$$

If we multiply both sides of this equation by $n!$ we get

$$\begin{aligned} m\cdot(n-1)! &= n!+\frac{n!}{1!}+\frac{n!}{2!}+\frac{n!}{3!}+\cdots+\frac{n!}{n!} \\ &\quad +\frac{1}{n+1}+\frac{1}{(n+1)(n+2)}+\frac{1}{(n+1)(n+2)(n+3)}+\cdots \\ &= \text{integer}+\frac{1}{n+1}+\frac{1}{(n+1)(n+2)} \\ &\quad +\frac{1}{(n+1)(n+2)(n+3)}+\cdots . \end{aligned}$$

The left-hand side of the equation is also an integer, so we conclude that

$$\frac{1}{n+1}+\frac{1}{(n+1)(n+2)}+\frac{1}{(n+1)(n+2)(n+3)}+\cdots \quad \text{is an integer.}$$

But clearly $n \geq 1$ (as the denominator of a fraction), so

$$\frac{1}{n+1}+\frac{1}{(n+1)(n+2)}+\frac{1}{(n+1)(n+2)(n+3)}+\cdots$$

$$<\frac{1}{2}+\frac{1}{2^2}+\frac{1}{2^3}+\cdots=1.$$

So $\frac{1}{n+1}+\frac{1}{(n+1)(n+2)}+\frac{1}{(n+1)(n+2)(n+3)}+\cdots$ is *not* an integer, and we have a contradiction. Thus it is false to assume that $e = m/n$. □

6.8 *The Inverse Tangent Function and π

Calculus is needed for geometry at quite an elementary level, to understand the circular functions sine, cosine, and tangent, and to evaluate the number π. To illustrate how calculus contributes to geometry, we are going to derive the simplest possible expression for π, namely,

$$\frac{\pi}{4}=1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\cdots\ .$$

This expression is a consequence of the power series for the inverse tangent function,

$$\arctan x = x-\frac{x^3}{3}+\frac{x^5}{5}-\frac{x^7}{7}+\cdots\ ,$$

which we derive first.

We view $y = \tan\theta$ as the vertical side of a right-angled triangle with horizontal side 1 and angle θ as shown in figure 6.14. Thus $\tan\theta = y$ is measured along the vertical tangent to the unit circle. Its inverse function $\theta = \arctan y$ is so called because θ is also the arc length on the unit circle spanned by the angle θ.

We now calculate $\frac{d}{dy}\arctan y = \frac{d\theta}{dy}$ by estimating the ratio $\frac{\Delta\theta}{\Delta y}$ when $\Delta\theta$ is a small addition to the angle θ, causing a small addition Δy to the height y on the vertical tangent (figure 6.15).

By the Pythagorean theorem, $OB = \sqrt{1+y^2}$, so the arc length $A'B$ subtended by the angle $\Delta\theta$ on the circle of radius $\sqrt{1+y^2}$ is

Consequently, the ratio of the sides Δy and $\Delta\theta\sqrt{1+y^2}$ of $BA'B'$ (corresponding to hypotenuse and base) approaches $\sqrt{1+y^2}$, so

$$\frac{\Delta\theta}{\Delta y} \to \frac{1}{1+y^2} \quad \text{as} \quad \Delta\theta \to 0.$$

In other words,

$$\frac{d}{dy}\arctan y = \frac{d\theta}{dy} = \frac{1}{1+y^2}.$$

$\Delta\theta\sqrt{1+y^2}$

Figure 6.15: Estimating the derivative of arctan y.

$\Delta\theta\sqrt{1+y^2}$. As $\Delta\theta \to 0$ this arc approaches a straight line segment and $BA'B'$ approaches a right-angled triangle similar to OAB. Consequently, the ratio of the sides Δy and $\Delta\theta\sqrt{1+y^2}$ of $BA'B'$ (corresponding to hypotenuse and base) approaches $\sqrt{1+y^2}$, so

$$\frac{\Delta\theta}{\Delta y} \to \frac{1}{1+y^2} \quad \text{as} \quad \Delta\theta \to 0.$$

In other words,

$$\frac{d}{dy}\arctan y = \frac{d\theta}{dy} = \frac{1}{1+y^2}.$$

It follows, integrating both sides, using $\arctan 0 = 0$ and the zero derivative theorem from section 6.3, that

$$\arctan x = \int_0^x \frac{dy}{1+y^2}.$$

Now we know from the theory of geometric series in section 6.1 that

$$\frac{1}{1+y^2} = 1 - y^2 + y^4 - y^6 + \cdots \quad \text{for} \quad |y| < 1.$$

Using this formula in the integral we get

$$\begin{aligned} \arctan x &= \int_0^x \left(1 - y^2 + y^4 - y^6 + \cdots\right)\, dy \quad \text{for} \quad |x| < 1 \\ &= \int_0^x 1\, dy - \int_0^x y^2\, dy + \int_0^x y^4\, dy - \int_0^x y^6\, dy + \cdots \\ &= x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \cdots\ . \end{aligned}$$

To justify the first step—from the integral of an infinite sum to the infinite sum of integrals—we proceed as we did in section 6.7, using the *finite* series

$$\frac{1}{1+y^2} = 1 - y^2 + y^4 - \cdots \pm y^{2n} \mp \frac{y^{2n+2}}{1+y^2}$$

and showing that $\int_0^x \frac{y^{2n+2}}{1+y^2}\, dy \to 0$ as n increases.

This more rigorous argument has another advantage: *the finite series is also valid for* $y = 1$. So we can conclude that

$$\arctan x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \cdots$$

is also valid for $x = 1$, which gives the wonderful formula

$$\frac{\pi}{4} = \arctan 1 = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \cdots\ .$$

6.9 Elementary Functions

We began this chapter by looking at functions we can differentiate: starting with constant and identity functions and quickly reaching all rational functions, by rules for differentiating $+$, $-$, $\cdot$, $\div$ of functions whose derivatives are known. The next two rules, for inverse functions and composite functions, allow us to differentiate many algebraic functions, such as $\sqrt{x}$, $\sqrt{1+x^2}$, $\sqrt[3]{1+x^4}$, $\ldots$, and so on. Finally, the fundamental theorem of calculus,

$$\frac{d}{dx}\int_a^x f(t)\,dt = f(x),$$

allows us to differentiate functions defined by integrals, such as

$$\ln x = \int_1^x \frac{dt}{t} \quad \text{and} \quad \arctan x = \int_0^x \frac{dt}{1+t^2}.$$

The functions obtainable from the latter two functions and rational functions by inversion, composition, and the rational operations $+$, $-$, $\cdot$, $\div$ are called the *elementary functions*. It may seem rather arbitrary to stop at the ln and arctan integrals—since many other functions are definable as integrals of algebraic functions—but there are good reasons to consider this the right place for elementary calculus to stop.

The main reason is that, assuming the fundamental theorem of algebra, the *integrals of all rational functions reduce to integrals of the* ln *or* arctan *type*. To see why, recall that any rational function of t can be written as a quotient of polynomials, $p(t)/q(t)$. It follows from the fundamental theorem of algebra that $q(t)$ is a product of real linear or quadratic factors

$$at + b \quad \text{or} \quad ct^2 + dt + e.$$

Then we can apply the algebraic technique of *partial fractions* (for an example, see section 7.3) to write $p(x)/q(x)$ as a sum of terms

$$\frac{A}{at+b} \quad \text{and} \quad \frac{Bt+C}{ct^2+dt+e}.$$

Some further easy transformations then reduce the integral of $p(t)/q(t)$ to integrals of $\frac{1}{t}$ and $\frac{1}{1+t^2}$; that is, to integrals of the ln or arctan type. Thus, *the integral of any rational function is an elementary function.*

This result shows that the elementary functions are not as arbitrary as they look. To reinforce this claim, we look at the elementary functions obtainable from the arctan function. Obviously, they include its inverse function, $\tan\theta$, but they also include the other circular functions, such as $\cos\theta$ and $\sin\theta$. We devote the next subsection to deriving the connection between the sine, cosine, and tangent functions, since it also has a beautiful connection with number theory and geometry.

Rational Points on the Circle

Ever since the discovery of the Pythagorean theorem there has been interest in *Pythagorean triples*: positive integer triples (a, b, c) such that $a^2 + b^2 = c^2$. The simplest Pythagorean triple is (3,4,5), and others are (5,12,13), (7,24,25), and (8,15,17). Specific Pythagorean triples have been known since ancient times in Europe, the Middle East, India, and China. Around 300 BCE, Euclid (*Elements*, Book X, lemma following Proposition 28) found a formula that gives them all:

$$a = (p^2 - q^2)r, \quad b = 2pqr, \quad c = (p^2 + q^2)r,$$

as p, q, r run through all positive integers.

A few centuries later, Diophantus transformed the problem of finding these triples into one about rational numbers, which can be viewed as finding *rational points on the unit circle*. This version of the problem arises because if $a^2 + b^2 = c^2$ then

$$\left(\frac{a}{c}\right)^2 + \left(\frac{b}{c}\right)^2 = 1,$$

so (a, b, c) corresponds to a rational point $\left(\frac{a}{c}, \frac{b}{c}\right)$ on the circle $x^2 + y^2 = 1$. This view of Pythagorean triples is revealing, because the search for them can now be guided by geometry and algebra. See figure 6.16.

If P has rational coordinates, then the slope t from Q to P is a rational number (because the "rise" and "run" are rational). Conversely, if the line PQ has rational slope t we can find P as the common solution

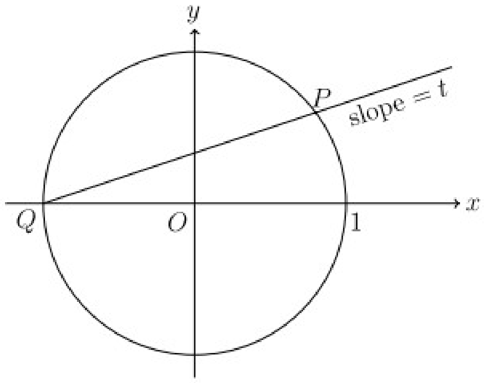

Figure 6.16: A rational point P on the unit circle.

of the linear equation

$$y = t(x+1) \qquad \text{(the equation of } PQ\text{)}$$

and the quadratic equation

$$x^2 + y^2 = 1 \qquad \text{(the equation of the unit circle).}$$

Since the coefficients of these two equations are rational, their common solutions are given by a quadratic equation in x with rational coefficients. We know that one of the solutions is $x = -1$ (for Q), so the second solution (giving the x-coordinate of P) must also be rational. We now work out exactly what the second solution is.

Substituting $y = t(x+1)$ in $x^2 + y^2 = 1$ gives the quadratic equation

$$x^2 + t^2(x+1)^2 = 1, \quad \text{that is,} \quad (1+t^2)x^2 + 2t^2x + t^2 - 1 = 0.$$

The quadratic formula gives the solutions

$$\begin{aligned} x &= \frac{-2t^2 \pm \sqrt{(2t^2)^2 - 4(1+t^2)(t^2-1)}}{2(1+t^2)} \\ &= \frac{-2t^2 \pm \sqrt{4t^4 - 4(t^4-1)}}{2(1+t^2)} \end{aligned}$$

$$= \frac{-2t^2 \pm 2}{2(1+t^2)}$$

$$= -1,\ \frac{1-t^2}{1+t^2}.$$

This confirms the solution $x = -1$ for Q, and gives $x = \frac{1-t^2}{1+t^2}$ as the x-coordinate of P. It follows from the equation of PQ that the y-coordinate of P is

$$y = t(x+1) = t\left(\frac{1-t^2+1+t^2}{1+t^2}\right) = \frac{2t}{1+t^2}.$$

Thus, *the rational points on* $x^2 + y^2 = 1$ *are* $(-1, 0)$ *and the points* $\left(\frac{1-t^2}{1+t^2}, \frac{2t}{1+t^2}\right)$ *as t runs through the rational numbers.*

For example, $t = \frac{1}{2}$ gives the point $\left(\frac{3}{5}, \frac{4}{5}\right)$ corresponding to the Pythagorean triple (3,4,5).

If we drop the restriction that t be rational, this makes no difference to the calculation of the coordinates of P,

$$x = \frac{1-t^2}{1+t^2}, \quad y = \frac{2t}{1+t^2}.$$

But now these formulas tell something interesting about the sine, cosine, and tangent functions, due to their association with the circle.

Sine and cosine formulas. *If* $t = \tan\frac{\theta}{2}$, *then*

$$\cos\theta = \frac{1-t^2}{1+t^2}, \quad \sin\theta = \frac{2t}{1+t^2}.$$

Proof. These formulas can be read off figure 6.17, once it is established that the angles are as shown. If we let θ be the angle between the line OP and the x-axis, then it is certainly true that $P = (\cos\theta, \sin\theta)$, by definition of the sine and cosine functions.

Also, it can be checked that $\theta/2$ is the angle of the line QP, using the facts that OPQ is an isosceles triangle, hence with equal angles at P and Q, and that the angle sum of a triangle is π.

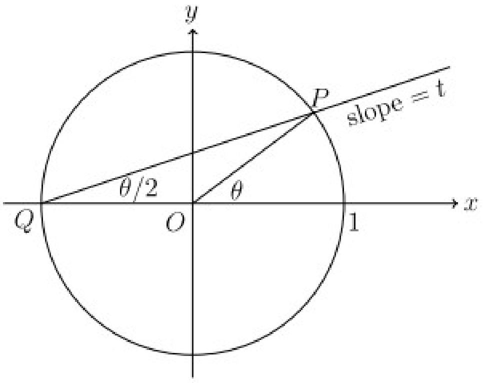

Figure 6.17: Angles in the circle.

Thus the slope t of PQ is $\tan \frac{\theta}{2}$, and hence

$$\left(\frac{1-t^2}{1+t^2}, \frac{2t}{1+t^2}\right) = (\cos\theta, \sin\theta),$$

which gives $\cos\theta = \frac{1-t^2}{1+t^2}$ and $\sin\theta = \frac{2t}{1+t^2}$. □

6.10 Historical Remarks

> Often I have considered the fact that most of the difficulties which block the progress of students trying to learn analysis stem from this: that although they understand little of ordinary algebra, still they attempt this more difficult art. From this it follows that they remain on the fringes, but in addition they entertain strange ideas about the concept of the infinite, which they must try to use.
>
> Euler (1748a), preface

Foundations of Calculus

Most of calculus as we know it, at the undergraduate level, was produced in a frenzy of activity in the late seventeenth and early eighteenth century. Both before and after that period there was concern about the

Foundations of Calculus

Most of calculus as we know it, at the undergraduate level, was produced in a frenzy of activity in the late seventeenth and early eighteenth century. Both before and after that period there was concern about the infinite processes that underlie the calculus—the foundations of calculus that we now call *analysis*. Infinite processes were already a concern in ancient Greece, and the Greeks devised the method of exhaustion to avoid infinity as far as possible. (Certainly, it avoids *actual* infinity.) As we saw in section 6.1, Archimedes used exhaustion to determine the area of the parabolic segment. It allowed him to conclude, using an "arbitrarily large" but not infinite number of triangles, that the area of the parabolic segment is 4/3 the area of the largest triangle.

The seventeenth-century mathematicians were well-schooled in the method of exhaustion, from Euclid and Archimedes, so they assumed they could fall back on it if necessary. But as Huygens (1659), p. 337, remarked:

> Mathematicians will never have enough time to read all the discoveries in Geometry (a quantity which is increasing from day to day and seems likely in this scientific age to develop to enormous proportions) if they continue to be presented in a rigorous form according to the manner of the ancients.

The idea that calculus could *in principle* be presented "in the manner of the ancients" might have been true in 1659, when mathematicians were still investigating curves individually. But after Newton and Leibniz made calculus truly a method of *calculation*, applicable to seemingly arbitrary formulas, the question of rigor became more acute.

When calculus became this general it was natural to ask: What is a function? What is a continuous function? Is it the same as a differentiable function? Newton, who thought of functions in terms of continuous motion, seemed to assume that continuous functions are both integrable and differentiable. As we now define continuity, continuous functions are integrable (on closed intervals) but some of them are *nowhere* differentiable. These results could not be known until the nineteenth century, when the concept of continuous function was first defined. The foundations of the definition were laid by Bolzano (1817) and Cauchy (1821), but the properties of continuous functions were not rigorously provable until Dedekind gave a definition of the continuum $\mathbb{R}$ of real numbers in 1858 (published in 1872). This started the push to arithmetize geometry and analysis, mentioned in section 5.10, after the discovery of non-Euclidean geometry.

With a definition of $\mathbb{R}$ finally available (Cantor, Meray, and Weierstrass published equivalent definitions of $\mathbb{R}$ about the same time as Dedekind), the calculus was put on a sound foundation by Weierstrass in the 1870s. It can still be asked (and perhaps can never be answered) whether the nineteenth-century foundations of calculus are the best possible, but most of the alternatives proposed so far give the same results, and are not noticeably simpler.

Preparing Students for Calculus

As we have seen, the foundations of calculus involve advanced ideas, particularly about infinity. This was realized long before the full extent of the problem became known, and mathematicians tried to devise appropriate and interesting material to *prepare* students for calculus, without exposing them to all the challenges of infinity. The most brilliant and fascinating book along these lines was the *Introductio in analysin infinitorum* (Introduction to the analysis of the infinite) of Euler (1748a).

In a nutshell, Euler believed that the best preparation for calculus was the study of infinite series. He had good reasons for believing this. As we have seen, infinite geometric series were implicitly used by Euclid and Archimedes, so infinite series were in use long before calculus. Another pointer from history was the contribution of Oresme (1350). He made the important discovery that the so-called *harmonic series*,

$$\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\frac{1}{5}+\cdots,$$

does not have a finite sum, even though its terms tend to zero. His proof was by collecting the terms into the following groups,

$$\begin{aligned}&\frac{1}{2}+\left(\frac{1}{3}+\frac{1}{4}\right)+\left(\frac{1}{5}+\frac{1}{6}+\frac{1}{7}+\frac{1}{8}\right)\\ &+\left(\frac{1}{9}+\frac{1}{10}+\frac{1}{11}+\frac{1}{12}+\frac{1}{13}+\frac{1}{14}+\frac{1}{15}+\frac{1}{16}\right)+\cdots,\end{aligned}$$

each of which has twice as many terms as the group before. It is easy to see that

$$\frac{1}{3}+\frac{1}{4}>\frac{2}{4}=\frac{1}{2},$$

$$\frac{1}{5}+\frac{1}{6}+\frac{1}{7}+\frac{1}{8}>\frac{4}{8}=\frac{1}{2},$$

$$\frac{1}{9}+\frac{1}{10}+\frac{1}{11}+\frac{1}{12}+\frac{1}{13}+\frac{1}{14}+\frac{1}{15}+\frac{1}{16}>\frac{8}{16}=\frac{1}{2},$$

and so on. Hence each of the infinitely many groups has sum $\geq \frac{1}{2}$, and so the sum of the series grows beyond all bounds. This discovery of Oresme was the first sign that sums of infinite series have some subtleties of their own.

Unknown to Euler, and to anyone else in Europe until the nineteenth century, was a collection of results giving a really spectacular demonstration that infinite series can be studied before calculus. These results, from the Indian mathematician Madhava, who lived around 1350–1425, include

$$\sin x = x-\frac{x^3}{3!}+\frac{x^5}{5!}-\frac{x^7}{7!}+\cdots\ ,$$

$$\cos x = 1-\frac{x^2}{2!}+\frac{x^4}{4!}-\frac{x^6}{6!}+\cdots\ ,$$

$$\tan^{-1} x = x-\frac{x^3}{3}+\frac{x^5}{5}-\frac{x^7}{7}+\cdots\ ,$$

the last of which gives a famous formula for π by substituting $x=1$:

$$\frac{\pi}{4}=1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\cdots\ .$$

For more on these results, whose discovery by Indian mathematicians was little known until recently, see Plofker (2009).

Finally, just before the dawn of calculus, Wallis (1655) discovered that

$$\frac{\pi}{2}=\frac{2\cdot 2}{1\cdot 3}\cdot\frac{4\cdot 4}{3\cdot 5}\cdot\frac{6\cdot 6}{5\cdot 7}\cdot\frac{8\cdot 8}{7\cdot 9}\cdot\cdots\ ,$$

and his colleague Lord Brouncker discovered the mysteriously similar result

$$\frac{\pi}{4} = \cfrac{1}{1 + \cfrac{1^2}{2 + \cfrac{3^2}{2 + \cfrac{5^2}{2 + \cfrac{7^2}{2 + \cfrac{9^2}{\ddots}}}}}}$$

One of Euler's achievements was to explain how the three formulas for π are related. The relation between the series and the continued fraction is explained in section 10.9.

Thus Euler had good reason to think that infinite series, and a few similar infinite processes, are a rich field that can be explored before embarking upon calculus. All of the above results actually appear in his book, together with many of Euler's own. Indeed, Euler is now considered to be the most brilliant and creative virtuoso of infinite series who ever lived, so it is no surprise that his *Introductio* goes well beyond the needs of a prospective calculus student. Nevertheless, we can all marvel at what he did.

For example, by comparing the power series for sine, cosine, and the exponential function, he discovered the formula

$$e^{i\theta} = \cos\theta + i\sin\theta,$$

with its miraculous special case

$$e^{i\pi} = -1.$$

And by multiplying geometric series together he discovered that, for any $s > 1$,

$$\left(\frac{1}{1-2^{-s}}\right)\left(\frac{1}{1-3^{-s}}\right)\left(\frac{1}{1-5^{-s}}\right)\cdots\left(\frac{1}{1-p^{-s}}\right)\cdots$$
$$= \frac{1}{1^s} + \frac{1}{2^s} + \frac{1}{3^s} + \frac{1}{4^s} + \frac{1}{5^s} + \cdots,$$

where p runs through all the prime numbers. The exponent $s > 1$ is there to ensure that the series on the right-hand side (the so-called *zeta* function of s) has a finite sum. For $s = 1$ the sum is infinite by Oresme's result, but this fact too is something we can exploit. If there are only finitely many primes, then the left side is *finite*, so we have a contradiction. Therefore, we have a new proof that there are infinitely many primes!

This result is just the first of a cornucopia of results about primes that fall out of Euler's formula.

The Geometric Series in Hardy's Pure Mathematics

> I have indeed in an examination asked a dozen candidates, including several future Senior Wranglers, to sum the series $1 + x + x^2 + \cdots$, and have not received a single answer that was not practically worthless—and this from men quite capable of solving difficult problems connected with the curvature and torsion of twisted curves.
>
> Hardy (1908), p. vi

The humble geometric series, which we have used as a foundation for much of this chapter, itself depends on a fundamental fact about limits: that $x^n \to 0$ as $n \to \infty$ when $|x| < 0$. For beginners, this fact seems obvious enough, and it was assumed in landmark works on the foundations of calculus, such as Cauchy (1821) and Jordan (1887). However, Hardy (1908), in his famous *Course of Pure Mathematics*, thought it worthwhile to probe more deeply, because his hope for his students was that

> accurate thought in connexion with these matters will become an integral part of their ordinary mathematical habit of mind. It is this conviction that has led me to devote so much space to the most elementary ideas of all connected with limits, to be purposely diffuse about fundamental points, to illustrate them by so elaborate a system of examples, and to write a chapter of fifty pages without advancing beyond the ordinary geometrical series.

EXAMPLE 1.8.2

Electromagnetic Wave Equations One important application of this vector relation [Eq. (1.96)] is in the derivation of the electromagnetic wave equation. In vacuum Maxwell's equations become

$$\nabla \cdot \mathbf{B} = 0, \tag{1.97a}$$

$$\nabla \cdot \mathbf{E} = 0, \tag{1.97b}$$

$$\nabla \times \mathbf{B} = \varepsilon_0 \mu_0 \frac{\partial \mathbf{E}}{\partial t} = \frac{1}{c^2}\frac{\partial \mathbf{E}}{\partial t}, \tag{1.97c}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \tag{1.97d}$$

where **E** is the electric field, **B** the magnetic induction, ε_0 the electric permittivity, and μ_0 the magnetic permeability (SI units), so that $\varepsilon_0\mu_0 = 1/c^2$, where c is the velocity of light. This relation has important consequences. Because ε_0, μ_0 can be measured in any frame, the velocity of light is the same in any frame.

Suppose we eliminate **B** from Eqs. (1.97c) and (1.97d). We may do this by taking the curl of both sides of Eq. (1.97d) and the time derivative of both sides of Eq. (1.97c). Since the space and time derivatives commute,

$$\frac{\partial}{\partial t}\nabla \times \mathbf{B} = \nabla \times \frac{\partial \mathbf{B}}{\partial t},$$

and we obtain

$$\nabla \times (\nabla \times \mathbf{E}) = -\frac{1}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2}.$$

Application of Eqs. (1.96) and (1.97b) yields

$$(\nabla \cdot \nabla)\mathbf{E} = \frac{1}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2}, \tag{1.98}$$

the electromagnetic vector wave equation. Again, if **E** is expressed in Cartesian coordinates, Eq. (1.98) separates into three scalar wave equations, each involving a scalar Laplacian.

When external electric charge and current densities are kept as driving terms in Maxwell's equations, similar wave equations are valid for the electric potential and the vector potential. To show this, we solve Eq. (1.97a) by writing $\mathbf{B} = \nabla \times \mathbf{A}$ as a curl of the vector potential. This expression is substituted into Faraday's induction law in differential form [Eq. (1.97d)] to yield $\nabla \times (\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t}) = 0$. The vanishing curl implies that $\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t}$ is a gradient and therefore can be written as $-\nabla\varphi$, where $\varphi(\mathbf{r}, t)$ is defined as the (nonstatic) electric potential. These results

$$\mathbf{B} = \nabla \times \mathbf{A}, \qquad \mathbf{E} = -\nabla\varphi - \frac{\partial \mathbf{A}}{\partial t} \tag{1.99}$$

for the **B** and **E** fields solve the homogeneous Maxwell's equations.

We now show that the inhomogeneous Maxwell's equations,

$$\text{Gauss's law: } \boldsymbol{\nabla}\cdot\mathbf{E} = \rho/\varepsilon_0;$$
$$\text{Oersted's law: } \boldsymbol{\nabla}\times\mathbf{B} - \frac{1}{c^2}\frac{\partial \mathbf{E}}{\partial t} = \mu_0\mathbf{J} \qquad (1.100)$$

in differential form lead to wave equations for the potentials φ and $\mathbf{A}$, provided that $\boldsymbol{\nabla}\cdot\mathbf{A}$ is determined by the constraint $\frac{1}{c^2}\frac{\partial\varphi}{\partial t} + \boldsymbol{\nabla}\cdot\mathbf{A} = 0$. This choice of fixing the divergence of the vector potential is called the **Lorentz gauge** and serves to uncouple the partial differential equations of both potentials. This gauge constraint is not a restriction; it has no physical effect.

Substituting our electric field solution into Gauss's law yields

$$\frac{\rho}{\varepsilon_0} = \boldsymbol{\nabla}\cdot\mathbf{E} = -\boldsymbol{\nabla}^2\varphi - \frac{\partial}{\partial t}\boldsymbol{\nabla}\cdot\mathbf{A} = -\boldsymbol{\nabla}^2\varphi + \frac{1}{c^2}\frac{\partial^2\varphi}{\partial t^2},$$

the wave equation for the electric potential. In the last step, we used the Lorentz gauge to replace the divergence of the vector potential by the time derivative of the electric potential and thus decouple φ from $\mathbf{A}$.

Finally, we substitute $\mathbf{B} = \boldsymbol{\nabla}\times\mathbf{A}$ into Oersted's law and use Eq. (1.96), which expands $\boldsymbol{\nabla}^2$ in terms of a longitudinal (the gradient term) and a transverse component (the curl term). This yields

$$\mu_0\mathbf{J} + \frac{1}{c^2}\frac{\partial\mathbf{E}}{\partial t} = \boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\mathbf{A}) = \boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\mathbf{A}) - \boldsymbol{\nabla}^2\mathbf{A} = \mu_0\mathbf{J} - \frac{1}{c^2}\left(\boldsymbol{\nabla}\frac{\partial\varphi}{\partial t} + \frac{\partial^2\mathbf{A}}{\partial t^2}\right),$$

where we have used the electric field solution [Eq. (1.99)] in the last step. Now we see that the Lorentz gauge condition eliminates the gradient terms so that the wave equation

$$\frac{1}{c^2}\frac{\partial^2\mathbf{A}}{\partial t^2} - \boldsymbol{\nabla}^2\mathbf{A} = \mu_0\mathbf{J}$$

for the vector potential remains.

Finally, looking back at Oersted's law, taking the divergence of Eq. (1.100), dropping $\boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}\times\mathbf{B}) = 0$ and substituting Gauss's law for $\boldsymbol{\nabla}\cdot\mathbf{E} = \rho/\epsilon_0$, we find $\mu_0\boldsymbol{\nabla}\cdot\mathbf{J} = -\frac{1}{\epsilon_0 c^2}\frac{\partial\rho}{\partial t}$, where $\epsilon_0\mu_0 = 1/c^2$, that is, the continuity equation for the current density. This step justifies the inclusion of Maxwell's displacement current in the generalization of Oersted's law to nonstationary situations. ■

EXERCISES

1.8.1 Verify Eq. (1.96)

$$\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\mathbf{V}) = \boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\mathbf{V}) - (\boldsymbol{\nabla}\cdot\boldsymbol{\nabla})\mathbf{V}$$

by direct expansion in Cartesian coordinates. If symbolic software is available, check the identity for typical fields, such as $\mathbf{V} = \mathbf{r}, \mathbf{r}/r^3, \mathbf{a}\cdot\mathbf{r}\mathbf{b}, \mathbf{a}\times\mathbf{r}$.

1.8.2 Show that the identity

$$\nabla \times (\nabla \times \mathbf{V}) = \nabla(\nabla \cdot \mathbf{V}) - (\nabla \cdot \nabla)\mathbf{V}$$

follows from the *BAC–CAB* rule for a triple vector product. Justify any alteration of the order of factors in the *BAC* and *CAB* terms.

1.8.3 Prove that $\nabla \times (\varphi \nabla \varphi) = 0$.

1.8.4 Prove that $(\nabla u) \times (\nabla v)$ is solenoidal, where u and v are differentiable scalar functions. Start by formulating the problem as a mathematical equation.

1.8.5 φ is a scalar satisfying Laplace's equation, $\nabla^2 \varphi = 0$. Show that $\nabla \varphi$ is **both** solenoidal and irrotational.

1.8.6 With ψ a scalar function, show that

$$(\mathbf{r} \times \nabla) \cdot (\mathbf{r} \times \nabla)\psi = r^2 \nabla^2 \psi - r^2 \frac{\partial^2 \psi}{\partial r^2} - 2r \frac{\partial \psi}{\partial r}.$$

(This can actually be shown more easily in spherical polar coordinates; see Section 2.5.)

1.8.7 In the Pauli theory of the electron one encounters the expression

$$(\mathbf{p} - e\mathbf{A}) \times (\mathbf{p} - e\mathbf{A})\psi,$$

where ψ is a scalar function. $\mathbf{A}$ is the magnetic vector potential related to the magnetic induction $\mathbf{B}$ by $\mathbf{B} = \nabla \times \mathbf{A}$. Given that $\mathbf{p} = -i\nabla$, show that this expression reduces to $ie\mathbf{B}\psi$. Show that this leads to the orbital g-factor $g_L = 1$ upon writing the magnetic moment as $\boldsymbol{\mu} = g_L \mathbf{L}$ in units of Bohr magnetons. See also Example 1.7.1.

1.8.8 Show that any solution of the equation

$$\nabla \times \nabla \times \mathbf{A} - k^2 \mathbf{A} = 0$$

automatically satisfies the vector Helmholtz equation

$$\nabla^2 \mathbf{A} + k^2 \mathbf{A} = 0$$

and the solenoidal condition

$$\nabla \cdot \mathbf{A} = 0.$$

Hint. Let $\nabla \cdot$ operate on the first equation.

1.9 Vector Integration

The next step after differentiating vectors is to integrate them. Let us start with line integrals and then proceed to surface and volume integrals. In each case, the method of attack will be to reduce the vector integral to one-dimensional integrals over a coordinate interval.

Line Integrals

Using an increment of length $dr = \hat{\mathbf{x}}\,dx + \hat{\mathbf{y}}\,dy + \hat{\mathbf{z}}\,dz$, we often encounter the line integral

$$\int_C \mathbf{V}\cdot d\mathbf{r}, \tag{1.101}$$

in which the integral is over some contour C that may be open (with starting point and ending point separated) or closed (forming a loop) instead of an interval of the x-axis. The Riemann integral is defined by subdividing the curve into ever smaller segments whose number grows indefinitely. The form [Eq. (1.101)] is exactly the same as that encountered when we calculate the work done by a force that varies along the path

$$W = \int \mathbf{F}\cdot d\mathbf{r} = \int F_x(x, y, z)\,dx + \int F_y(x, y, z)\,dy + \int F_z(x, y, z)\,dz, \tag{1.102}$$

that is, a sum of conventional integrals over intervals of one variable each. In this expression, $\mathbf{F}$ is the force exerted on a particle. In general, such integrals depend on the path except for conservative forces, whose treatment we postpone to Section 1.12.

EXAMPLE 1.9.1

Path-Dependent Work The force exerted on a body is $\mathbf{F} = -\hat{\mathbf{x}}y + \hat{\mathbf{y}}x$. The problem is to calculate the work done going from the origin to the point (1, 1),

$$W = \int_{0,0}^{1,1} \mathbf{F}\cdot d\mathbf{r} = \int_{0,0}^{1,1} (-y\,dx + x\,dy). \tag{1.103}$$

Separating the two integrals, we obtain

$$W = -\int_0^1 y\,dx + \int_0^1 x\,dy. \tag{1.104}$$

The first integral cannot be evaluated until we specify the values of y as x ranges from 0 to 1. Likewise, the second integral requires x as a function of y. Consider first the path shown in Fig. 1.27. Then

$$W = -\int_0^1 0\,dx + \int_0^1 1\,dy = 1 \tag{1.105}$$

because $y = 0$ along the first segment of the path and $x = 1$ along the second. If we select the path $[x = 0, 0 \le y \le 1]$ and $[0 \le x \le 1, y = 1]$, then Eq. (1.103) gives $W = -1$. For this force, the work done depends on the choice of path. ■

EXAMPLE 1.9.2

Line Integral for Work Find the work done going around a unit circle clockwise from 0 to $-\pi$ shown in Fig. 1.28 in the xy-plane doing work against a force field given by

$$\mathbf{F} = \frac{-\hat{\mathbf{x}}y}{x^2+y^2} + \frac{\hat{\mathbf{y}}x}{x^2+y^2}.$$

Figure 1.27

A Path of Integration

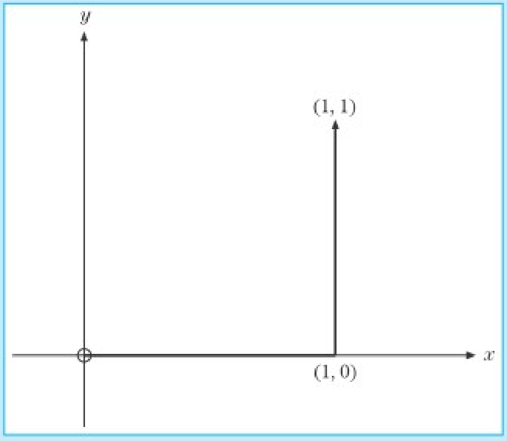

Figure 1.28

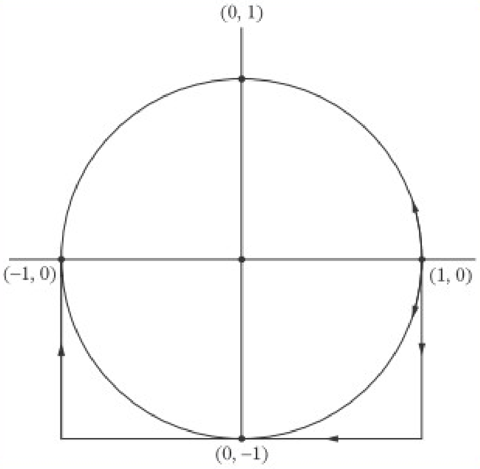
Circular and Square Integration Paths



Let us parameterize the circle C as $x = \cos\varphi$, $y = \sin\varphi$ with the polar angle φ so that $dx = -\sin\varphi d\varphi$, $dy = \cos\varphi d\varphi$. Then the force can be written as $\mathbf{F} = -\hat{\mathbf{x}}\sin\varphi + \hat{\mathbf{y}}\cos\varphi$. The work becomes

$$-\int_C \frac{xdy - ydx}{x^2 + y^2} = \int_0^{-\pi} (-\sin^2\varphi - \cos^2\varphi)\, d\varphi = \pi.$$

Here we spend energy. If we integrate anticlockwise from $\varphi = 0$ to π we find the value $-\pi$ because we are riding with the force. The work is path dependent, which is consistent with the physical interpretation that $\mathbf{F} \cdot d\mathbf{r} \sim xdy - ydx = L_z$ is proportional to the z-component of orbital angular momentum (involving circulation, as discussed in Section 1.7).

If we integrate along the square through the points $(\pm 1, 0)$, $(0, -1)$ surrounding the circle, we find for the clockwise lower half square path of Fig. 1.28

$$\begin{aligned}
-\int \mathbf{F} \cdot d\mathbf{r} &= -\int_0^{-1} F_y \, dy|_{x=1} - \int_1^{-1} F_x \, dx|_{y=-1} - \int_{-1}^{0} F_y \, dy|_{x=-1} \\
&= \int_0^1 \frac{dy}{1+y^2} + \int_{-1}^{1} \frac{dx}{x^2+(-1)^2} + \int_{-1}^{0} \frac{dy}{(-1)^2+y^2} \\
&= \arctan(1) + \arctan(1) - \arctan(-1) - \arctan(-1) \\
&= 4 \cdot \frac{\pi}{4} = \pi,
\end{aligned}$$

which is consistent with the circular path.

For the circular paths we used the $x = \cos\varphi$, $y = \sin\varphi$ parameterization, whereas for the square shape we used the standard definitions $y = f(x)$ or $x = g(y)$ of a curve, that is, $y = -1 = \text{const.}$ and $x = \pm 1 = \text{const.}$ We could have used the implicit definition $F(x, y) \equiv x^2 + y^2 - 1 = 0$ of the circle. Then the total variation

$$dF = \frac{\partial F}{\partial x} dx + \frac{\partial F}{\partial y} dy = 2x \, dx + 2y \, dy \equiv 0$$

so that

$$dy = -x \, dx/y \text{ with } y = -\sqrt{1-x^2}$$

on our half circle. The work becomes

$$\begin{aligned}
-\int_C \frac{x \, dy - y \, dx}{x^2+y^2} = \int \left(\frac{x^2}{y} + y \right) dx = \int \frac{dx}{y} = \int_1^{-1} \frac{dx}{-\sqrt{1-x^2}} \\
= \arcsin 1 - \arcsin(-1) = 2 \cdot \frac{\pi}{2} = \pi,
\end{aligned}$$

in agreement with our previous results. ■

EXAMPLE 1.9.3

Gravitational Potential If a force can be described by a scalar function V_G as $\mathbf{F} = -\nabla V_G(\mathbf{r})$ [Eq. (1.65)], everywhere we call V_G its potential in mechanics and engineering. Because the total variation $dV_G = \nabla V_G \cdot d\mathbf{r} = -\mathbf{F}_G \cdot d\mathbf{r}$ is the work done against the force along the path $d\mathbf{r}$, the integrated work along any path from the initial point $\mathbf{r}_0$ to the final point $\mathbf{r}$ is given by a line integral $\int_{\mathbf{r}_0}^{\mathbf{r}} dV_G = V_G(\mathbf{r}) - V_G(\mathbf{r}_0)$, the potential difference between the end points of the path. Thus, to find the scalar potential for the gravitational force on a unit mass m_1,

$$\mathbf{F}_G = -\frac{Gm_1m_2\hat{\mathbf{r}}}{r^2} = -\frac{k\hat{\mathbf{r}}}{r^2}, \quad \text{radially } \textbf{inward} \tag{1.106}$$

we integrate from infinity, where V_G is zero into position $\mathbf{r}$. We obtain

$$V_G(r) - V_G(\infty) = -\int_{\infty}^{\mathbf{r}} \mathbf{F}_G \cdot d\mathbf{r} = +\int_{\mathbf{r}}^{\infty} \mathbf{F}_G \cdot d\mathbf{r}. \tag{1.107}$$

By use of $\mathbf{F}_G = -\mathbf{F}_{\text{applied}}$, the potential is the work done in bringing the unit mass in from infinity. (We can define only the potential difference. Here, we arbitrarily assign infinity to be a zero of potential.) Since $\mathbf{F}_G$ is radial, we obtain a contribution to V_G only when $d\mathbf{r}$ is radial or

$$V_G(r) = -\int_{r}^{\infty} \frac{k\,dr}{r^2} = -\frac{k}{r} = -\frac{Gm_1m_2}{r}. \tag{1.108}$$

The negative sign reflects the attractive nature of gravity. ■

Surface Integrals

Surface integrals appear in the same forms as line integrals, the element of area also being a vector, $d\boldsymbol{\sigma}$.[13] Often this area element is written $\mathbf{n}\,dA$, where $\mathbf{n}$ is a unit (normal) vector to indicate the positive direction.[14] There are two conventions for choosing the positive direction. First, if the surface is a closed surface, we agree to take the outward normal as positive. Second, if the surface is an open surface, the positive normal depends on the direction in which the perimeter of the open surface is traversed. If the right-hand fingers are curled in the direction of travel around the perimeter, the positive normal is indicated by the thumb of the right hand. As an illustration, a circle in the xy-plane (Fig. 1.29) mapped out from x to y to $-x$ to $-y$ and back to x will have its positive normal parallel to the positive z-axis (for the right-handed coordinate system).

Analogous to the line integrals, Eq. (1.101), surface integrals may appear in the form

$$\int \mathbf{V} \cdot d\boldsymbol{\sigma}. \tag{1.109}$$

This surface integral $\int \mathbf{V} \cdot d\boldsymbol{\sigma}$ may be interpreted as a flow or flux through the given surface. This is really what we did in Section 1.6 to understand the significance of the concept of divergence. Note that both physically and from the dot product the tangential components of the velocity contribute nothing to the flow through the surface.

---

[13] Recall that in Section 1.3 the area (of a parallelogram) is represented by a cross product **vector**.

[14] Although $\mathbf{n}$ always has unit length, its direction may well be a function of position.

Figure 1.29

Right-Hand Rule for the Positive Normal

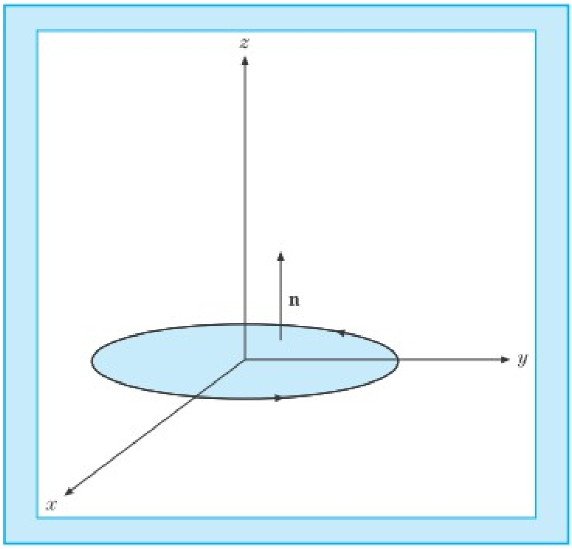


Figure 1.30

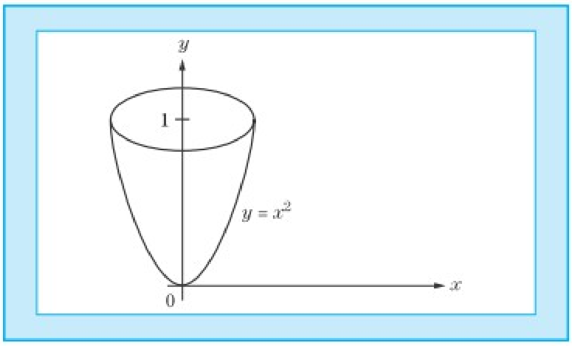
The Parabola $y = x^2$ for $0 \le y \le 1$ Rotated About the y-Axis



EXAMPLE 1.9.4

Moment of Inertia Let us determine the moment of inertia I_y of a segment of the parabola $y = x^2$ cut off by the line $y = 1$ and rotated about the y-axis (Fig. 1.30). We find

$$I_y = 2\mu \int_{x=0}^{1} \int_{y=x^2}^{1} x^2 \, dx \, dy = 2\mu \int_0^1 (1 - x^2) x^2 dx = 2\mu \left(\frac{x^3}{3} - \frac{x^5}{5} \right) \Big|_0^1 = \frac{4\mu}{15}.$$

The factor of 2 originates in the reflection symmetry of $x \to -x$, and μ is the constant mass density. ■

A surface in three-dimensional space may be explicitly given as $z = f(x, y)$ or by the coordinate functions of its points

$$x = x(u, v), \quad y = y(u, v), \quad z = z(u, v)$$

in terms of two parameters u, v or in implicit form $F(x, y, z) = 0$. The explicit form is a special case

$$F(x, y, z) \equiv z - f(x, y)$$

of the general implicit definition of a surface. We find the area $dA = dx\,dy/n_z$ over the projection $dx\,dy$ of the surface onto the xy-plane for the latter case. Here, $n_z = \cos\gamma$ is the z-component of the normal unit vector $\mathbf{n}$ at $\mathbf{r}$ on the surface so that γ is the angle of $d\mathbf{A}$ with the xy-plane. Thus, when we project $d\mathbf{A}$ to the xy-plane, we get $dA\cos\gamma = dx\,dy$, which proves this useful formula for measuring the **area of a curved surface**. From the gradient properties we also know that $\mathbf{n} = \nabla f/\sqrt{\nabla f^2}$.

EXAMPLE 1.9.5

A Surface Integral Here we apply the general formula for surface integrals to find the area on $z = xy = f(x, y)$ cut out by the unit circle in the xy-plane shown in Fig. 1.31. We start from

$$\frac{\partial f}{\partial x} = \frac{\partial z}{\partial x} = y, \quad \frac{\partial f}{\partial y} = \frac{\partial z}{\partial y} = x, \quad \frac{\partial f}{\partial z} = \frac{\partial z}{\partial z} = 1,$$

which we substitute into

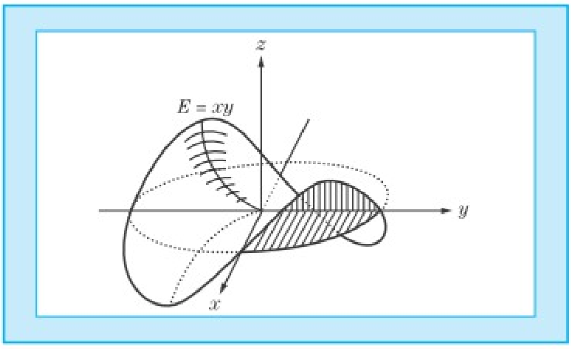
$$n_z = 1\Big/\sqrt{1 + \left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2}$$

for the normal to yield the area

$$A = \int_{x=-1}^{x=1} \int_{y=-\sqrt{1-x^2}}^{y=\sqrt{1-x^2}} \sqrt{1 + x^2 + y^2}\, dx\, dy.$$

Figure 1.31

The Surface $z = xy$ Above and Below the Unit Circle $x^2 + y^2 = 1$



For the circular geometry plane polar coordinates r, φ are more appropriate, where the radial integral is evaluated by substituting $u = 1 + r^2$ in

$$A = \int_0^1 \sqrt{1+r^2}\,r\,dr \int_0^{2\pi} d\varphi = \pi \int \sqrt{u}\,du = \frac{2\pi}{3}\left|(1+r^2)^{3/2}\right|_0^1 = \frac{2\pi}{3}(2\sqrt{2}-1).$$

■

More examples of line and surface integrals are provided in Chapter 2.

Volume Integrals

Volume integrals are simpler because the volume element $d\tau$ is a scalar quantity.[15] We have

$$\int_v \mathbf{V}\,d\tau = \hat{\mathbf{x}}\int_v V_x\,d\tau + \hat{\mathbf{y}}\int_v V_y\,d\tau + \hat{\mathbf{z}}\int_v V_z\,d\tau, \tag{1.110}$$

again reducing the vector integral to a vector sum of scalar integrals.

If the vector

$$\mathbf{V} = V_\rho(\rho,\varphi,z)\hat{\boldsymbol{\rho}} + V_\varphi(\rho,\varphi,z)\hat{\boldsymbol{\varphi}} + V_z(\rho,\varphi,z)\hat{\mathbf{z}}$$

and its components are given in cylindrical coordinates $x = \rho\cos\varphi$, $y = \rho\sin\varphi$ with volume element $d\tau = \rho\,d\rho\,d\varphi\,dz$, the volume integral

$$\int_v \mathbf{V}\,d\tau = \hat{\mathbf{z}}\int_v V_z\,d\tau + \int\!\!\int\!\!\int (V_\rho\hat{\boldsymbol{\rho}} + V_\varphi\hat{\boldsymbol{\varphi}})\rho\,d\rho\,d\varphi\,dz$$

involves integrals over the varying unit vectors of the polar coordinates. To reduce them to scalar integrals, we need to expand the polar coordinate unit vectors in Cartesian unit vectors as follows. Dividing the plane coordinates by ρ, we find

$$\hat{\boldsymbol{\rho}} = \frac{1}{\rho}(x, y) = (\cos\varphi, \sin\varphi) = \hat{\mathbf{x}}\cos\varphi + \hat{\mathbf{y}}\sin\varphi.$$

Differentiating $\hat{\boldsymbol{\rho}}^2 = 1$, we see from $0 = \frac{d\hat{\boldsymbol{\rho}}^2}{d\varphi} = 2\hat{\boldsymbol{\rho}}\cdot\frac{d\hat{\boldsymbol{\rho}}}{d\varphi}$ that

$$\frac{d\hat{\boldsymbol{\rho}}}{d\varphi} = -\hat{\mathbf{x}}\sin\varphi + \hat{\mathbf{y}}\cos\varphi = \hat{\boldsymbol{\varphi}}$$

is perpendicular to $\hat{\boldsymbol{\rho}}$ and a unit vector; therefore, it is equal to $\hat{\boldsymbol{\varphi}}$. Substituting these expressions into the second integral yields the final result

$$\begin{aligned}\int_v \mathbf{V}\,d\tau &= \hat{\mathbf{z}}\int_v V_z\,d\tau + \hat{\mathbf{x}}\int\!\!\int\!\!\int [V_\rho\cos\varphi - V_\varphi\sin\varphi]\rho\,d\rho\,d\varphi\,dz \\ &\quad + \hat{\mathbf{y}}\int\!\!\int\!\!\int [V_\rho\sin\varphi + V_\varphi\cos\varphi]\rho\,d\rho\,d\varphi\,dz.\end{aligned} \tag{1.111}$$

The terms in brackets are the Cartesian components V_x, V_y expressed in plane polar coordinates.

---

[15] Frequently, the symbols d^3r and d^3x are used to denote a volume element in coordinate (xyz or $x_1x_2x_3$) space.

In spherical polar coordinates, all of the unit vectors depend on the coordinates, none can be pulled out of the integrals, and all have to be expanded in Cartesian unit vectors. This task of rewriting Eq. (1.110) is left as an exercise.

EXAMPLE 1.9.6

Volume of Rotated Gaussian Rotate the Gaussian $y = \exp(-x^2)$ about the z-axis leading to $z = \exp(-x^2 - y^2)$. Then the volume in the polar (cylindrical) coordinates appropriate for the geometry is given by

$$V = \int_{r=0}^{\infty} \int_{\varphi=0}^{2\pi} \int_{z=0}^{e^{-r^2}} r\,dr\,d\varphi\,dz = 2\pi \int_0^{\infty} re^{-r^2} dr = \pi \int_0^{\infty} e^{-u} du = \pi,$$

upon substituting $\exp(-x^2 - y^2) = \exp(-r^2)$, $dx\,dy = r\,dr\,d\varphi$, $u = r^2$, and $du = 2rdr$. ■

Integral Definitions of Gradient, Divergence, and Curl

One interesting and significant application of our surface and volume integrals is their use in developing alternate definitions of our differential relations. We find

$$\nabla\varphi = \lim_{\int d\tau \to 0} \frac{\int \varphi\, d\boldsymbol{\sigma}}{\int d\tau}, \tag{1.112}$$

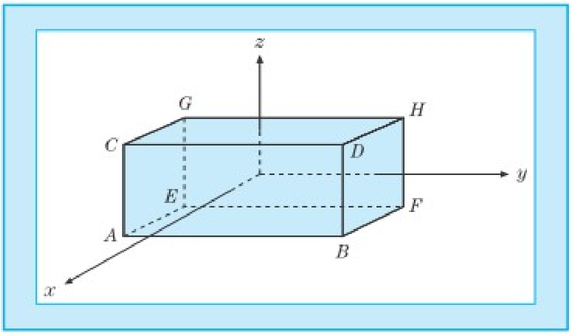
$$\nabla \cdot \mathbf{V} = \lim_{\int d\tau \to 0} \frac{\int \mathbf{V} \cdot d\boldsymbol{\sigma}}{\int d\tau}, \tag{1.113}$$

$$\nabla \times \mathbf{V} = \lim_{\int d\tau \to 0} \frac{\int d\boldsymbol{\sigma} \times \mathbf{V}}{\int d\tau}. \tag{1.114}$$

In these three equations, $\int d\tau$ is the volume of a small region of space and $d\boldsymbol{\sigma}$ is the vector area element of this volume. The identification of Eq. (1.113) as the divergence of **V** was carried out in Section 1.6. Here, we show that Eq. (1.112) is consistent with our earlier definition of $\nabla\varphi$ [Eq. (1.64)]. For simplicity, we choose $d\tau$ to be the differential volume $dx\,dy\,dz$ (Fig. 1.32). This

Figure 1.32

Differential Rectangular Parallelepiped (Origin at Center)



time, we place the origin at the geometric center of our volume element. The area integral leads to six integrals, one for each of the six faces. Remembering that $d\boldsymbol{\sigma}$ is outward, $d\boldsymbol{\sigma} \cdot \hat{\mathbf{x}} = -|d\boldsymbol{\sigma}|$ for surface *EFHG*, and $+|d\boldsymbol{\sigma}|$ for surface *ABDC*, we have

$$\begin{aligned}\int \varphi\, d\boldsymbol{\sigma} = {}& -\hat{\mathbf{x}} \int_{EFHG} \left(\varphi - \frac{\partial \varphi}{\partial x}\frac{dx}{2}\right) dy\,dz + \hat{\mathbf{x}} \int_{ABDC} \left(\varphi + \frac{\partial \varphi}{\partial x}\frac{dx}{2}\right) dy\,dz \\ & -\hat{\mathbf{y}} \int_{AEGC} \left(\varphi - \frac{\partial \varphi}{\partial y}\frac{dy}{2}\right) dx\,dz + \hat{\mathbf{y}} \int_{BFHD} \left(\varphi + \frac{\partial \varphi}{\partial y}\frac{dy}{2}\right) dx\,dz \\ & -\hat{\mathbf{z}} \int_{ABFE} \left(\varphi - \frac{\partial \varphi}{\partial z}\frac{dz}{2}\right) dx\,dy + \hat{\mathbf{z}} \int_{CDHG} \left(\varphi + \frac{\partial \varphi}{\partial z}\frac{dz}{2}\right) dx\,dy.\end{aligned}$$

Using the first two terms of a Maclaurin expansion, we evaluate each integrand at the origin with a correction included to correct for the displacement ($\pm dx/2$, etc.) of the center of the face from the origin. Having chosen the total volume to be of differential size ($\int d\tau = dx\,dy\,dz$), we drop the integral signs on the right and obtain

$$\int \varphi\, d\boldsymbol{\sigma} = \left(\hat{\mathbf{x}}\frac{\partial \varphi}{\partial x} + \hat{\mathbf{y}}\frac{\partial \varphi}{\partial y} + \hat{\mathbf{z}}\frac{\partial \varphi}{\partial z}\right) dx\,dy\,dz. \tag{1.115}$$

Dividing by

$$\int d\tau = dx\,dy\,dz,$$

we verify Eq. (1.112).

This verification has been oversimplified in ignoring other correction terms beyond the first derivatives. These additional terms, which are introduced in Section 5.6 when the Taylor expansion is developed, vanish in the limit

$$\int d\tau \to 0\,(dx \to 0,\, dy \to 0,\, dz \to 0).$$

This, of course, is the reason for specifying in Eqs. (1.112)–(1.114) that this limit be taken. Verification of Eq. (1.114) follows these same lines, using a differential volume $d\tau = dx\,dy\,dz$.

EXERCISES

1.9.1 Find the potential for the electric field generated by a charge q at the origin. Normalize the potential to zero at spatial infinity.

1.9.2 Determine the gravitational field of the earth taken to be spherical and of uniform mass density. Punch out a concentric spherical cavity and show that the field is zero inside it. Show that the field is constant if the cavity is not concentric.

5- NT2< 3

1.9.3 Evaluate

$$\frac{1}{3}\int_s \mathbf{r}\cdot d\boldsymbol{\sigma}$$

over the unit cube defined by the point (0, 0, 0) and the unit intercepts on the positive x-, y-, and z-axes. Note that (a) $\mathbf{r}\cdot d\boldsymbol{\sigma}$ is zero for three of the surfaces, and (b) each of the three remaining surfaces contributes the same amount to the integral.

1.9.4 Show by expansion of the surface integral that

$$\lim_{\int d\tau\to 0}\frac{\int_s d\boldsymbol{\sigma}\times\mathbf{V}}{\int d\tau}=\boldsymbol{\nabla}\times\mathbf{V}.$$

Hint. Choose the volume to be a differential volume, $dx\,dy\,dz$.

1.10 Gauss's Theorem

Here, we derive a useful relation between a surface integral of a vector and the volume integral of the divergence of that vector. Let us assume that the vector **V** and its first derivatives are continuous over the simply connected region (without holes) of interest. Then, **Gauss's theorem** states that

$$\int_S \mathbf{V}\cdot d\boldsymbol{\sigma}=\int_V \boldsymbol{\nabla}\cdot\mathbf{V}\,d\tau. \qquad (1.116\text{a})$$

In words, the surface integral of a vector over a closed surface equals the volume integral of the divergence of that vector integrated over the volume enclosed by the surface.

Imagine that volume V is subdivided into an arbitrarily large number of tiny (differential) parallelepipeds. For each parallelepiped,

$$\sum_{\text{six surfaces}}\mathbf{V}\cdot d\boldsymbol{\sigma}=\boldsymbol{\nabla}\cdot\mathbf{V}\,d\tau \qquad (1.116\text{b})$$

from the analysis of Section 1.6, Eq. (1.75), with $\rho\mathbf{v}$ replaced by **V**. The summation is over the six faces of the parallelepiped. Summing over all parallelepipeds, we find that the $\mathbf{V}\cdot d\boldsymbol{\sigma}$ terms cancel (pairwise) for all **interior** faces; only the contributions of the **exterior** surfaces survive (Fig. 1.33). Analogous to the definition of a Riemann integral as the limit of a sum, we take the limit as the number of parallelepipeds approaches infinity (→ ∞) and the dimensions of each approach zero (→ 0):

$$\sum_{\text{exterior surfaces}}\mathbf{V}\cdot_{\downarrow} d\boldsymbol{\sigma}=\sum_{\text{volumes}}\boldsymbol{\nabla}\cdot_{\downarrow}\mathbf{V}\,d\tau$$

$$\int_S \mathbf{V}\cdot d\boldsymbol{\sigma}=\int_V \boldsymbol{\nabla}\cdot\mathbf{V}\,d\tau.$$

The result is Eq. (1.116a), Gauss's theorem.

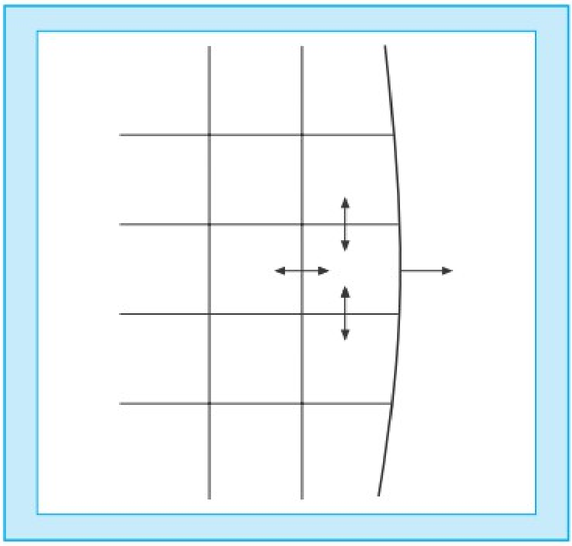


Figure 1.33

Exact Cancellation of $\mathbf{V} \cdot d\boldsymbol{\sigma}$'s on Interior Surfaces. No Cancellation on the Exterior Surface

From a physical standpoint, Eq. (1.75) has established $\nabla \cdot \mathbf{V}$ as the net outflow of field per unit volume. The volume integral then gives the total net outflow. However, the surface integral $\int \mathbf{V} \cdot d\boldsymbol{\sigma}$ is just another way of expressing this same quantity, which is the equality, Gauss's theorem.

Biographical Data

Gauss, Carl Friedrich. Gauss, a German mathematician, physicist, and astronomer, was born in Brunswick in 1777 and died in Göttingen in 1855. He was an infant prodigy in mathematics whose education was directed and financed by the Duke of Brunswick. As a teenager, he proved that regular n-polygons can be constructed in Euclidean geometry provided n is a Fermat prime number such as 3, 5, 17, and 257, a major advance in geometry since antiquity. This feat convinced him to stay in mathematics and give up the study of foreign languages. For his Ph.D., he proved the fundamental theorem of algebra, avoiding the then controversial complex numbers he had used to discover it. In his famous treatise *Disquisitiones Arithmetica* on number theory, he first proved the quadratic reciprocity theorem and originated the terse style and rigor of mathematical proofs as a series of logical steps, discarding any trace of the original heuristic ideas used in the discovery and checks of examples. Not surprisingly, he hated teaching. He is considered by many as the greatest mathematician of all times and was the last to provide major contributions to all then existing branches of mathematics. As the founder of differential geometry, he developed the intrinsic properties of surfaces, such as curvature, which later motivated B. Riemann to develop the geometry of metric spaces, the mathematical foundation of Einstein's General Relativity. In astronomy (for the orbit of the asteroid Ceres), he developed the method of least squares for fitting curves to data. In physics, he developed potential theory, and the unit of the magnetic induction is named after him in honor of his measurements and development of units in physics.

Green's Theorem

A frequently useful corollary of Gauss's theorem is a relation known as Green's theorem. If u and v are two scalar functions, we have the identities

$$\nabla \cdot (u\,\nabla v) = u\nabla \cdot \nabla v + (\nabla u) \cdot (\nabla v), \tag{1.117}$$

$$\nabla \cdot (v\,\nabla u) = v\nabla \cdot \nabla u + (\nabla v) \cdot (\nabla u), \tag{1.118}$$

which follow from the product rule of differentiation. Subtracting Eq. (1.118) from Eq. (1.117), integrating over a volume (u, v, and their derivatives, assumed continuous), and applying Eq. (1.116a) (Gauss's theorem), we obtain

$$\int_V (u\nabla \cdot \nabla v - v\nabla \cdot \nabla u)\,d\tau = \int_S (u\nabla v - v\nabla u) \cdot d\boldsymbol{\sigma}. \tag{1.119}$$

This is **Green's theorem**, which states that the antisymmetric Laplacian of a pair of functions integrated over a simply connected volume (no holes) is equivalent to the antisymmetric gradient of the pair integrated over the bounding surface. An alternate form of Green's theorem derived from Eq. (1.117) alone is

$$\int_S u\nabla v \cdot d\boldsymbol{\sigma} = \int_V u\nabla \cdot \nabla v\,d\tau + \int_V \nabla u \cdot \nabla v\,d\tau. \tag{1.120}$$

Finally, Gauss's theorem may also be extended to tensors (see Section 2.11).

Biographical Data

Green, George. Green, an English mathematician, was born in Nottingham in 1793 and died near Nottingham in 1841. He studied Laplace's papers in Cambridge and developed potential theory in electrodynamics.

EXERCISES

1.10.1 If $\mathbf{B} = \nabla \times \mathbf{A}$, show that

$$\int_S \mathbf{B} \cdot d\boldsymbol{\sigma} = 0$$

for any closed surface S. State this in words. If symbolic software is available, check this for a typical vector potential and specific surfaces, such as a sphere or cube.

1.10.2 Over some volume V, let ψ be a solution of Laplace's equation (with the derivatives appearing there continuous). Prove that the integral over any closed surface in V of the normal derivative of ψ ($\partial\psi/\partial n$, or $\nabla\psi\cdot\mathbf{n}$) will be zero.

1.10.3 In analogy to the integral definition of gradient, divergence, and curl of Section 1.10, show that

$$\nabla^2\varphi = \lim_{\int d\tau\to 0}\frac{\int \nabla\varphi\cdot d\boldsymbol{\sigma}}{\int d\tau}.$$

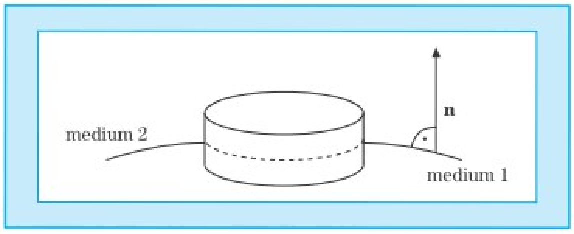
1.10.4 The electric displacement vector $\mathbf{D}$ satisfies the Maxwell equation $\nabla\cdot\mathbf{D} = \rho$, where ρ is the charge density (per unit volume). At the boundary between two media there is a surface charge density σ (per unit area). Show that a boundary condition for $\mathbf{D}$ is

$$(\mathbf{D}_2 - \mathbf{D}_1)\cdot\mathbf{n} = \sigma,$$

where $\mathbf{n}$ is a unit vector normal to the surface and out of medium 1. *Hint.* Consider a thin pillbox as shown in Fig. 1.34.

Figure 1.34

Pillbox



1.10.5 From Eq. (1.77) and Example 1.6.1, with $\mathbf{V}$ the electric field $\mathbf{E}$ and f the electrostatic potential φ, show that

$$\int \rho\varphi\, d\tau = \varepsilon_0 \int E^2\, d\tau.$$

This corresponds to a three-dimensional integration by parts.
Hint. $\mathbf{E} = -\nabla\varphi$, $\nabla\cdot\mathbf{E} = \rho/\varepsilon_0$. You may assume that φ vanishes at large r at least as fast as r^{-1}.

1.10.6 The creation of a **localized** system of steady electric currents (current density $\mathbf{J}$) and magnetic fields may be shown to require an amount of work

$$W = \frac{1}{2}\int \mathbf{H}\cdot\mathbf{B}\, d\tau.$$

Transform this into

$$W = \frac{1}{2}\int \mathbf{J}\cdot\mathbf{A}\, d\tau,$$

where $\mathbf{A}$ is the magnetic vector potential, $\nabla\times\mathbf{A} = \mathbf{B}$.

Hint. In Maxwell's equations, take the displacement current term $\partial\mathbf{D}/\partial t = 0$ and explain why using Ohm's law. If the fields and currents are localized, a bounding surface may be taken far enough out so that the integrals of the fields and currents over the surface yield zero.

1.11 Stokes's Theorem

Gauss's theorem relates the volume integral of a derivative of a function to an integral of the function over the closed surface bounding the volume. Here, we consider an analogous relation between the surface integral of a derivative of a function and the line integral of the function, the path of integration being the perimeter bounding the surface.

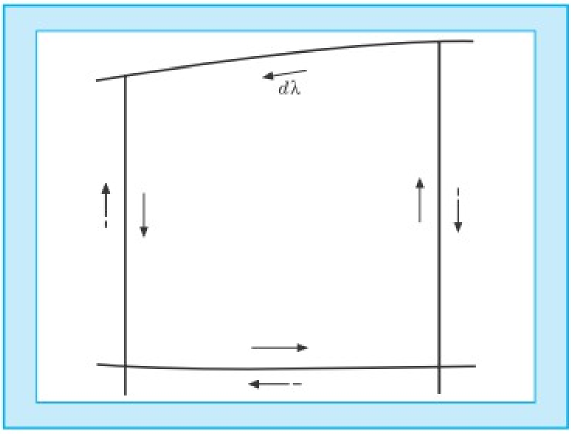
Let us take the surface and subdivide it into a network of arbitrarily small rectangles. In Section 1.7, we showed that the circulation about such a differential rectangle (in the xy-plane) is $\nabla \times \mathbf{V}|_z \; dx\,dy$. From Eq. (1.85) applied to **one** differential rectangle,

$$\sum_{\text{four sides}} \mathbf{V} \cdot d\boldsymbol{\lambda} = \nabla \times \mathbf{V} \cdot d\boldsymbol{\sigma}. \tag{1.121}$$

We sum over all the little rectangles as in the definition of a Riemann integral. The surface contributions [right-hand side of Eq. (1.121)] are added together. The line integrals [left-hand side of Eq. (1.121)] of all **interior** line segments cancel identically. Only the line integral around the perimeter survives (Fig. 1.35). Taking the usual limit as the number of rectangles approaches

Figure 1.35

Exact Cancellation on Interior Paths; No Cancellation on the Exterior Path



infinity while $dx \to 0$, $dy \to 0$, we have

$$\begin{array}{ccc} \displaystyle\sum_{\substack{\text{exterior line}\\ \text{segments}}} \mathbf{V}\cdot d\boldsymbol{\lambda} & = & \displaystyle\sum_{\text{rectangles}} \boldsymbol{\nabla}\times\mathbf{V}\cdot d\boldsymbol{\sigma} \\ \downarrow & & \downarrow \\ \displaystyle\oint \mathbf{V}\cdot d\boldsymbol{\lambda} & = & \displaystyle\int_S \boldsymbol{\nabla}\times\mathbf{V}\cdot d\boldsymbol{\sigma}. \end{array} \tag{1.122}$$

This is Stokes's theorem. The surface integral on the right is over the surface bounded by the perimeter or contour for the line integral on the left. The direction of the vector representing the area is out of the paper plane toward the reader if the direction of traversal around the contour for the line integral is in the positive mathematical sense as shown in Fig. 1.35.

This demonstration of Stokes's theorem is limited by the fact that we used a Maclaurin expansion of $\mathbf{V}(x, y, z)$ in establishing Eq. (1.85) in Section 1.7. Actually, we need only demand that the curl of $\mathbf{V}(x, y, z)$ exists and that it be integrable over the surface. Stokes's theorem obviously applies to an open, simply connected surface. It is possible to consider a closed surface as a limiting case of an open surface with the opening (and therefore the perimeter) shrinking to zero. This is the point of Exercise 1.11.4.

As a special case of Stokes's theorem, consider the curl of a two-dimensional vector field $\mathbf{V} = (V_1(x, y), V_2(x, y), 0)$. The curl $\boldsymbol{\nabla}\times\mathbf{V} = (0, 0, \frac{\partial V_2}{\partial x} - \frac{\partial V_1}{\partial y})$ so

$$\int_S \boldsymbol{\nabla}\times\mathbf{V}\cdot\hat{\mathbf{z}}\,dx\,dy = \int_S \left(\frac{\partial V_2}{\partial x} - \frac{\partial V_1}{\partial y}\right) dx\,dy = \int_C \mathbf{V}\cdot d\mathbf{r} = \int_C (V_1 dx + V_2 dy),$$

where the curve C is the boundary of the simply connected surface S that is integrated in the positive mathematical sense (anticlockwise). This relation is sometimes also called Green's theorem. In Chapter 6, we shall use it to prove Cauchy's theorem for analytic functions.

EXAMPLE 1.11.1

Area as a Line Integral For the two-dimensional Stokes's theorem, we first choose $\mathbf{V} = x\hat{\mathbf{y}}$, which gives the area $S = \int_S dx\,dy = \int_C x\,dy$, and for $\mathbf{V} = (y\hat{\mathbf{x}})$ we get similarly $S = \int_S dx\,dy = -\int_C y\,dx$. Adding both results gives the area

$$S = \frac{1}{2}\int_C (x\,dy - y\,dx). \quad ■$$

We can use Stokes's theorem to derive Oersted's and Faraday's laws from two of Maxwell's equations and vice versa, thus recognizing that the former are an integrated form of the latter.

EXAMPLE 1.11.2

Oersted's and Faraday's Laws Consider the magnetic field generated by a long wire that carries a stationary current I (Fig. 1.36). Starting from Maxwell's differential law $\boldsymbol{\nabla}\times\mathbf{H} = \mathbf{J}$ [Eq. (1.97c); with Maxwell's displacement current $\partial\mathbf{D}/\partial t = 0$ for a stationary current case by Ohm's law], we integrate over a closed area S perpendicular to and surrounding the wire and apply Stokes's

Figure 1.36

Oersted's Law for a Long Wire Carrying a Current

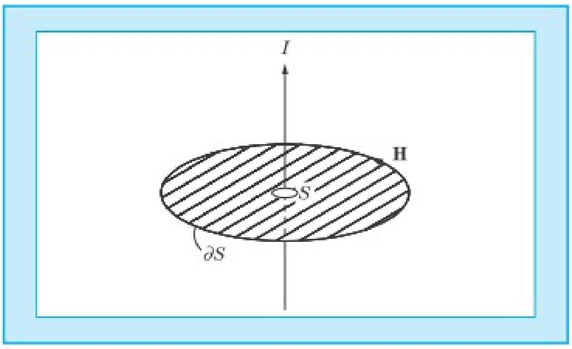


Figure 1.37

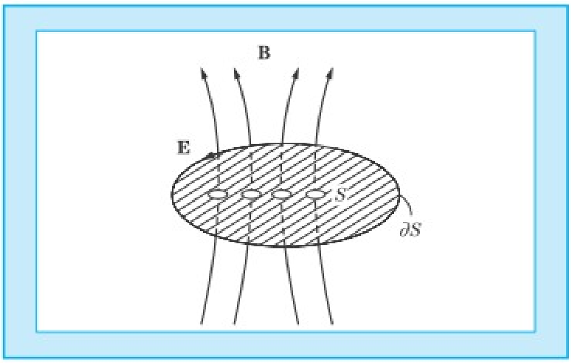
Faraday's Induction Law Across a Magnetic Induction Field



theorem to get

$$I = \int_S \mathbf{J} \cdot d\boldsymbol{\sigma} = \int_S (\boldsymbol{\nabla} \times \mathbf{H}) \cdot d\boldsymbol{\sigma} = \oint_{\partial S} \mathbf{H} \cdot d\mathbf{r},$$

which is Oersted's law. Here, the line integral is along ∂S, the closed curve surrounding the cross section area S.

Similarly, we can integrate Maxwell's equation for $\boldsymbol{\nabla} \times \mathbf{E}$ [Eq. (1.97d)] to yield Faraday's induction law. Imagine moving a closed loop (∂S) of wire (of area S) across a magnetic induction field $\mathbf{B}$ (Fig. 1.37). At a fixed moment of time we integrate Maxwell's equation and use Stokes's theorem, yielding

$$\int_{\partial S} \mathbf{E} \cdot d\mathbf{r} = \int_S (\boldsymbol{\nabla} \times \mathbf{E}) \cdot d\boldsymbol{\sigma} = -\frac{d}{dt} \int_S \mathbf{B} \cdot d\boldsymbol{\sigma} = -\frac{d\Phi}{dt},$$

which is Faraday's law. The line integral on the left-hand side represents the voltage induced in the wire loop, whereas the right-hand side is the change with time of the magnetic flux Φ through the moving surface S of the wire. ■

SUMMARY

Both Stokes's and Gauss's theorems are of tremendous importance in a wide variety of problems involving vector calculus in electrodynamics, where they allow us to derive the local form of Maxwell's differential equations from the global (integral) form of the experimental laws. An indication of their power and versatility may be obtained from the exercises in Sections 1.10 and 1.11 and the development of potential theory in Section 1.12.

Biographical Data

Stokes, Sir George Gabriel. Stokes, a British mathematician and physicist, was born in Skreen, Ireland, in 1819 and died in Cambridge in 1903. Son of a clergyman, his talent for mathematics was already evident in school. In 1849, he became Lucasian professor at Cambridge, the chair Isaac Newton once held and currently held by S. Hawking. In 1885, he became president of the Royal Society. He is known for the theory of viscous fluids, with practical applications to the motion of ships in water. He demonstrated his vision by hailing Joule's work early on and recognizing X-rays as electromagnetic radiation. He received the Rumford and Copley medals of the Royal Society and served as a member of Parliament for Cambridge University in 1887–1892.

EXERCISES

1.11.1 The calculation of the magnetic moment of a current loop leads to the line integral

$$\oint \mathbf{r} \times d\mathbf{r}.$$

(a) Integrate around the perimeter of a current loop (in the xy-plane) and show that the scalar magnitude of this line integral is twice the area of the enclosed surface.

(b) The perimeter of an ellipse is described by $\mathbf{r} = \hat{\mathbf{x}}a\cos\theta + \hat{\mathbf{y}}b\sin\theta$. From part (a), show that the area of the ellipse is πab.

1.11.2 In steady state, the magnetic field $\mathbf{H}$ satisfies the Maxwell equation $\nabla \times \mathbf{H} = \mathbf{J}$, where $\mathbf{J}$ is the current density (per square meter). At the boundary between two media there is a surface current density $\mathbf{K}$ (perimeter). Show that a boundary condition on $\mathbf{H}$ is

$$\mathbf{n} \times (\mathbf{H}_2 - \mathbf{H}_1) = \mathbf{K},$$

where $\mathbf{n}$ is a unit vector normal to the surface and out of medium 1. *Hint.* Consider a narrow loop perpendicular to the interface as shown in Fig. 1.38.

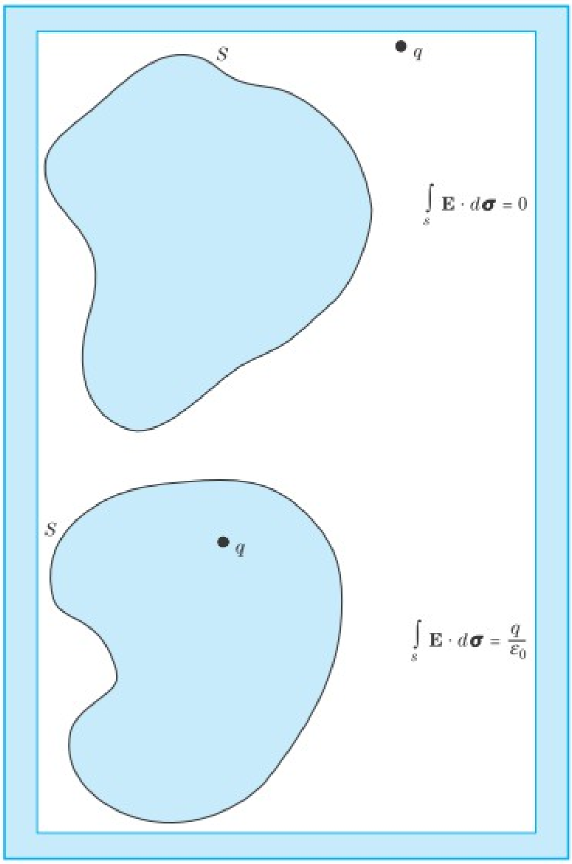
Gauss's Law



S
q
$\int_S \mathbf{E} \cdot d\boldsymbol{\sigma} = 0$
S
q
$\int_S \mathbf{E} \cdot d\boldsymbol{\sigma} = \frac{q}{\varepsilon_0}$

1.13 Gauss's Law and Poisson's Equation

Gauss's Law

Consider a point electric charge q at the origin of our coordinate system. This produces an electric field $\mathbf{E}$[16] given by

$$\mathbf{E} = \frac{q\hat{\mathbf{r}}}{4\pi\varepsilon_0 r^2}. \tag{1.136}$$

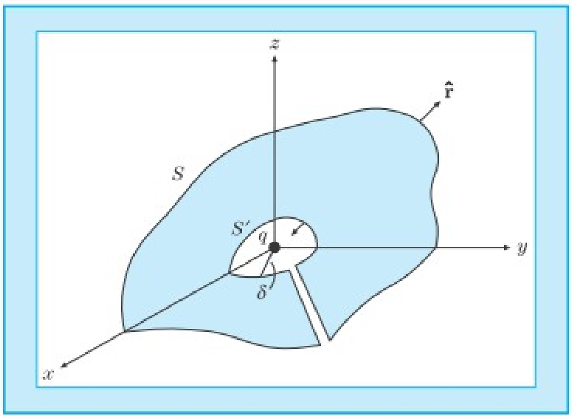
We now derive Gauss's law, which states that the surface integral in Fig. 1.42 is q/ε_0 if the closed surface S includes the origin (where q is located) and zero

---

[16] The electric field $\mathbf{E}$ is defined as the force per unit charge on a small stationary test charge q_t: $\mathbf{E} = \mathbf{F}/q_t$. From Coulomb's law, the force on q_t due to q is $\mathbf{F} = (qq_t/4\pi\varepsilon_0)(\hat{\mathbf{r}}/r^2)$. When we divide by q_t, Eq. (1.136) follows.

Figure 1.43

Exclusion of the Origin



if the surface does not include the origin. The surface S is any closed surface; it need not be spherical.

Using Gauss's theorem [Eq. (1.116a)] (and neglecting the scale factor $q/4\pi\varepsilon_0$), we obtain

$$\int_S \frac{\hat{\mathbf{r}}\cdot d\boldsymbol{\sigma}}{r^2} = \int_V \nabla\cdot\left(\frac{\hat{\mathbf{r}}}{r^2}\right) d\tau = 0 \tag{1.137}$$

by Example 1.6.1, provided the surface S does not include the origin, where the integrands are not defined. This proves the second part of Gauss's law.

The first part, in which the surface S must include the origin, may be handled by surrounding the origin with a small sphere S' of radius δ (Fig. 1.43). So that there will be no question as to what is inside and what is outside, imagine the volume outside the outer surface S and the volume inside surface $S'(r < \delta)$ connected by a small hole. This joins surfaces S and S', combining them into one **single, simply connected closed surface**. Because the radius of the imaginary hole may be made vanishingly small, there is no additional contribution to the surface integral. The inner surface is deliberately chosen to be spherical so that we will be able to integrate over it. Gauss's theorem now applies to the volume between S and S' without any difficulty. We have

$$\int_S \frac{\hat{\mathbf{r}}\cdot d\boldsymbol{\sigma}}{r^2} + \int_{S'} \frac{\hat{\mathbf{r}}\cdot d\boldsymbol{\sigma}'}{\delta^2} = 0. \tag{1.138}$$

We may evaluate the second integral for $d\boldsymbol{\sigma}' = -\hat{\mathbf{r}}\delta^2\, d\Omega$, in which $d\Omega$ is an element of solid angle. The minus sign appears because we agreed in Section 1.9 to have the positive normal $\hat{\mathbf{r}}'$ **outward** from the volume. In this case, the outward $\hat{\mathbf{r}}'$ is in the negative radial direction, $\hat{\mathbf{r}}' = -\hat{\mathbf{r}}$. By integrating over all angles, we have

$$\int_{S'} \frac{\hat{\mathbf{r}}\cdot d\boldsymbol{\sigma}'}{\delta^2} = -\int_{S'} \frac{\hat{\mathbf{r}}\cdot\hat{\mathbf{r}}\delta^2 d\Omega}{\delta^2} = -4\pi, \tag{1.139}$$

independent of the radius δ. With the constants from Eq. (1.136), this results in

$$\int_S \mathbf{E}\cdot d\boldsymbol{\sigma} = \frac{q}{4\pi\varepsilon_0}4\pi = \frac{q}{\varepsilon_0}, \tag{1.140}$$

completing the proof of Gauss's law. Notice that although the surface S may be spherical, it **need not** be spherical.

Going a bit further, we consider a distributed charge so that

$$q = \int_V \rho\, d\tau. \tag{1.141}$$

Equation (1.140) still applies, with q now interpreted as the total distributed charge enclosed by surface S:

$$\int_S \mathbf{E}\cdot d\boldsymbol{\sigma} = \int_V \frac{\rho}{\varepsilon_0}\, d\tau. \tag{1.142}$$

Using Gauss's theorem, we have

$$\int_V \boldsymbol{\nabla}\cdot\mathbf{E}\, d\tau = \int_V \frac{\rho}{\varepsilon_0}\, d\tau. \tag{1.143}$$

Since our volume is completely arbitrary, the integrands must be equal or

$$\boldsymbol{\nabla}\cdot\mathbf{E} = \frac{\rho}{\varepsilon_0}, \tag{1.144}$$

one of Maxwell's equations. If we reverse the argument, Gauss's law follows immediately from Maxwell's equation by integration.

Poisson's Equation

Replacing $\mathbf{E}$ by $-\boldsymbol{\nabla}\varphi$, Eq. (1.144) becomes

$$\boldsymbol{\nabla}\cdot\boldsymbol{\nabla}\varphi = -\frac{\rho}{\varepsilon_0}, \tag{1.145}$$

which is Poisson's equation. We know a solution,

$$\varphi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0}\int \frac{\rho(\mathbf{r}')d\tau'}{|\mathbf{r}-\mathbf{r}'|},$$

from generalizing a sum of Coulomb potentials for discrete charges in electrostatics to a continuous charge distribution.

For the condition $\rho = 0$ this reduces to an even more famous equation, the **Laplace equation**.

$$\boldsymbol{\nabla}\cdot\boldsymbol{\nabla}\varphi = 0. \tag{1.146}$$

We encounter Laplace's equation frequently in discussing various curved coordinate systems (Chapter 2) and the special functions of mathematical physics that appear as its solutions in Chapter 11.

From direct comparison of the Coulomb electrostatic force law and Newton's law of universal gravitation,

$$\mathbf{F}_E = \frac{1}{4\pi\varepsilon_0}\frac{q_1q_2}{r^2}\hat{\mathbf{r}}, \qquad \mathbf{F}_G = -G\frac{m_1m_2}{r^2}\hat{\mathbf{r}}.$$

All of the potential theory of this section therefore applies equally well to gravitational potentials. For example, the gravitational Poisson equation is

$$\nabla \cdot \nabla \varphi = +4\pi G\rho, \tag{1.147}$$

with ρ now a mass density.

Biographical Data

Poisson, Siméon Denis. Poisson, a French mathematician, was born in Pithiviers, France in 1781 and died in Paris in 1840. He studied mathematics at the Ecole Polytechnique under Laplace and Lagrange, whom he so impressed with his talent that he became professor there in 1802. He contributed to their celestial mechanics, Fourier's heat theory, and probability theory, among others.

EXERCISES

1.13.1 Develop Gauss's law for the two-dimensional case in which

$$\varphi = -q\frac{\ln \rho}{2\pi \varepsilon_0}, \quad \mathbf{E} = -\nabla\varphi = q\frac{\hat{\boldsymbol{\rho}}}{2\pi\varepsilon_0\rho},$$

where q is the charge at the origin or the line charge per unit length if the two-dimensional system is a unit thickness slice of a three-dimensional (circular cylindrical) system. The variable ρ is measured radially outward from the line charge. $\hat{\boldsymbol{\rho}}$ is the corresponding unit vector (see Section 2.2). If graphical software is available, draw the potential and field for the $q/2\pi\varepsilon_0 = 1$ case.

1.13.2 (a) Show that Gauss's law follows from Maxwell's equation

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\varepsilon_0}$$

by integrating over a closed surface. Here, ρ is the charge density.

(b) Assuming that the electric field of a point charge q is spherically symmetric, show that Gauss's law implies the Coulomb inverse square expression

$$\mathbf{E} = \frac{q\hat{\mathbf{r}}}{4\pi\varepsilon_0 r^2}.$$

1.13.3 Show that the value of the electrostatic potential φ at any point P is equal to the average of the potential over any spherical surface centered on P. There are no electric charges on or within the sphere.

Hint. Use Green's theorem [Eq. (1.119)], with $u^{-1} = r$, the distance from P, and $v = \varphi$.

1.13.4 Using Maxwell's equations, show that for a system (steady current) the magnetic vector potential $\mathbf{A}$ satisfies a vector Poisson equation

$$\nabla^2\mathbf{A} = -\mu\mathbf{J},$$

provided we require $\nabla \cdot \mathbf{A} = 0$ in Coulomb gauge.

1.14 Dirac Delta Function

From Example 1.6.1 and the development of Gauss's law in Section 1.13,

$$\int \nabla \cdot \nabla \left(\frac{1}{r}\right) d\tau = -\int \nabla \cdot \left(\frac{\hat{\mathbf{r}}}{r^2}\right) d\tau = \begin{cases} -4\pi \\ 0 \end{cases}, \tag{1.148}$$

depending on whether the integration includes the origin $\mathbf{r} = 0$ or not. This result may be conveniently expressed by introducing the Dirac delta function,

$$\nabla^2 \left(\frac{1}{r}\right) = -4\pi\,\delta\,(\mathbf{r}) = -4\pi\,\delta(x)\delta(y)\delta(z). \tag{1.149}$$

This Dirac delta function is **defined** by its assigned properties

$$\delta\,(x) = 0, \qquad x \neq 0 \tag{1.150}$$

$$f\,(0) = \int_{-\infty}^{\infty} f\,(x)\,\delta(x)\,dx, \tag{1.151}$$

where $f(x)$ is any well-behaved function and the integration includes the origin. As a special case of Eq. (1.151),

$$\int_{-\infty}^{\infty} \delta(x)\,dx = 1. \tag{1.152}$$

From Eq. (1.151), $\delta(x)$ must be an infinitely high, infinitely thin spike at $x = 0$, as in the description of an impulsive force or the charge density for a point charge.[17] The problem is that **no such function exists** in the usual sense of function. However, the crucial property in Eq. (1.151) can be developed rigorously as the limit of a **sequence** of functions, a distribution. For example, the delta function may be approximated by the sequences of functions in n for $n \to \infty$ [Eqs. (1.153)–(1.156) and Figs. 1.44–1.47]:

$$\delta_n(x) = \begin{cases} 0, & x < -\frac{1}{2n} \\ n, & -\frac{1}{2n} < x < \frac{1}{2n} \\ 0, & x > \frac{1}{2n} \end{cases} \tag{1.153}$$

$$\delta_n(x) = \frac{n}{\sqrt{\pi}} \exp(-n^2x^2) \tag{1.154}$$

$$\delta_n(x) = \frac{n}{\pi} \cdot \frac{1}{1 + n^2x^2} \tag{1.155}$$

$$\delta_n(x) = \frac{\sin nx}{\pi x} = \frac{1}{2\pi} \int_{-n}^{n} e^{ixt}\,dt. \tag{1.156}$$

---

[17] The delta function is frequently invoked to describe very short-range forces such as nuclear forces. It also appears in the normalization of continuum wave functions of quantum mechanics.

Figure 1.44

δ Sequence Function Eq. (1.153)

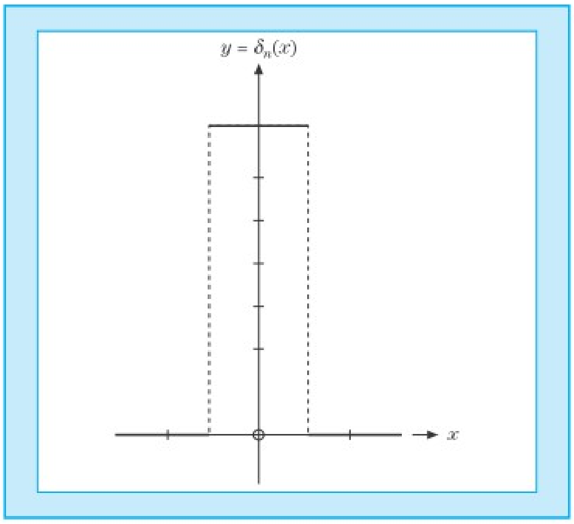


Figure 1.45

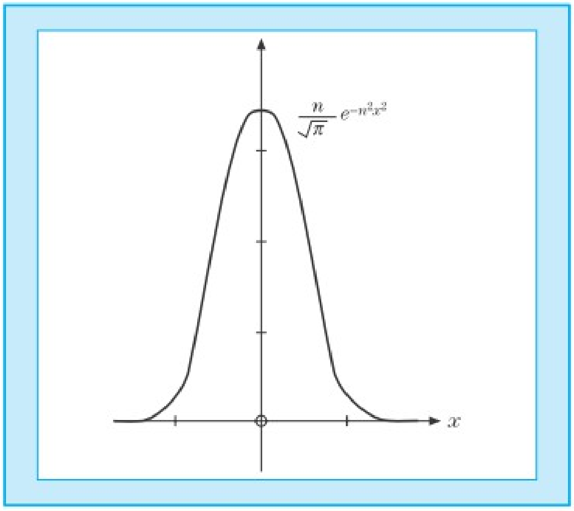
δ Sequence Function Eq. (1.154)



EXAMPLE 1.14.1 Let us evaluate $\int_{-\pi}^{\pi} \cos x\delta(x)dx = \cos 0 = 1$ using the sequence of Eq. (1.153). We find

$$\int_{-1/2n}^{1/2n} n\cos x\, dx = n\sin x|_{-1/2n}^{1/2n} = n\left(\sin\left(\frac{1}{2n}\right) - \sin\left(-\frac{1}{2n}\right)\right)$$

$$= 2n\sin\frac{1}{2n} = 2n\left(\frac{1}{2n} + O(1/n^3)\right) \to 1 \text{ for } n \to \infty.$$

Figure 1.46

δ Sequence Function Eq. (1.155)

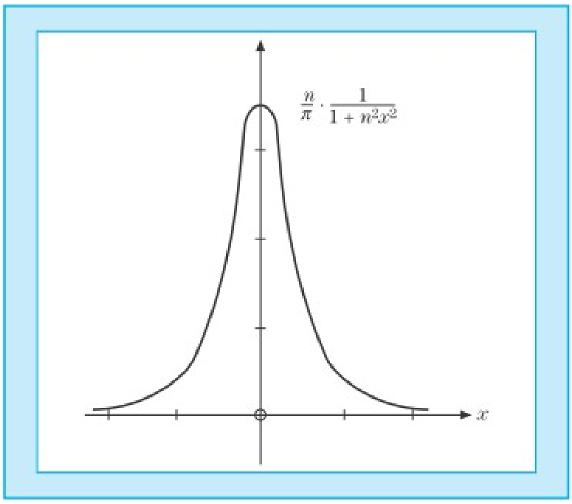


Figure 1.47

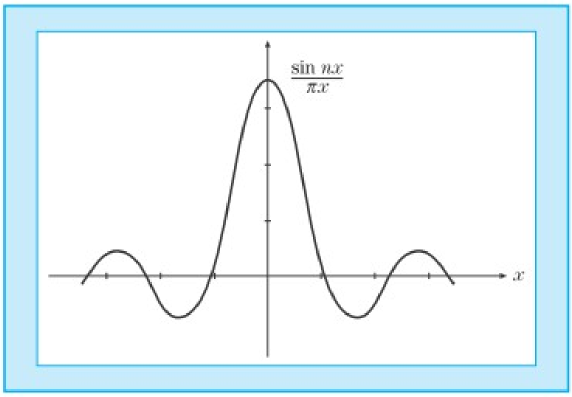
δ Sequence Function Eq. (1.156)



Notice how the integration limits change in the first step. Similarly, $\int_{-\pi}^{\pi} \sin x\delta(x) \cdot dx = \sin 0 = 0$. We could have used Eq. (1.155) instead,

$$\begin{aligned}
\frac{n}{\pi}\int_{-\pi}^{\pi}\frac{\cos x\,dx}{1+n^2x^2} &= \frac{n}{\pi}\int_{-\pi}^{\pi}\frac{1-x^2/2+\cdots}{1+n^2x^2}dx = \frac{n}{\pi}\int_{-\pi}^{\pi}\frac{dx}{1+n^2x^2}\\
&= \frac{1}{\pi}\int_{-n\pi}^{n\pi}\frac{dy}{1+y^2} = \frac{1}{\pi}[\arctan(n\pi) - \arctan(-n\pi)]\\
&= \frac{2}{\pi}\arctan(n\pi) \to \frac{2}{\pi}\frac{\pi}{2} = 1, \quad \text{for } n \to \infty,
\end{aligned}$$

by keeping just the first term of the power expansion of $\cos x$. Again, we could have changed the integration limits to $\pm\pi/n$ in the first step for all terms with positive powers of x because the denominator is so large, except close to $x = 0$ for large n. This explains why the higher order terms of the $\cos x$ power series do not contribute. ■

These approximations have varying degrees of usefulness. Equation (1.153) is useful in providing a simple derivation of the integral property [Eq. (1.151)]. Equation (1.154) is convenient to differentiate. Its derivatives lead to the Hermite polynomials. Equation (1.156) is particularly useful in Fourier analysis and in its applications to quantum mechanics. In the theory of Fourier series, Eq. (1.156) often appears (modified) as the Dirichlet kernel:

$$\delta_n(x) = \frac{1}{2\pi}\frac{\sin[(n+\frac{1}{2})x]}{\sin(\frac{1}{2}x)}. \tag{1.157}$$

In using these approximations in Eq. (1.151) and later, we assume that $f(x)$ is integrable—it offers no problems at large x.

For most physical purposes such approximations are quite adequate. From a mathematical standpoint, the situation is still unsatisfactory: The limits

$$\lim_{n\to\infty} \delta_n(x)$$

do not exist.

A way out of this difficulty is provided by the theory of distributions. Recognizing that Eq. (1.151) is the fundamental property, we focus our attention on it rather than on $\delta(x)$. Equations (1.153)–(1.156), with $n = 1, 2, 3, \ldots$, may be interpreted as **sequences** of normalized functions:

$$\int_{-\infty}^{\infty} \delta_n(x)\,dx = 1. \tag{1.158}$$

The sequence of integrals has the limit

$$\lim_{n\to\infty}\int_{-\infty}^{\infty} \delta_n(x) f(x)\,dx = f(0). \tag{1.159}$$

Note that Eq. (1.158) is the limit of a sequence of integrals. Again, the limit of $\delta_n(x)$, $n\to\infty$, does not exist. [The limits for all four forms of $\delta_n(x)$ diverge at $x = 0$.]

We may treat $\delta(x)$ consistently in the form

$$\int_{-\infty}^{\infty} \delta(x) f(x)\,dx = \lim_{n\to\infty}\int_{-\infty}^{\infty} \delta_n(x) f(x)\,dx. \tag{1.160}$$

$\delta(x)$ is labeled a distribution (not a function) defined by the sequences $\delta_n(x)$ as indicated in Eq. (1.158). We might emphasize that the integral on the left-hand side of Eq. (1.160) is not a Riemann integral.[18] It is a limit.

---

[18] It can be treated as a Stieltjes integral if desired. $\delta(x)\,dx$ is replaced by $du(x)$, where $u(x)$ is the Heaviside step function.

This distribution $\delta(x)$ is only one of an infinity of possible distributions, but it is the one we are interested in because of Eq. (1.151).

From these sequences of functions, we see that Dirac's delta function must be even in x, $\delta(-x) = \delta(x)$.

Let us now consider a detailed application of the Dirac delta function to a single charge and illustrate the singularity of the electric field at the origin.

EXAMPLE 1.14.2

Total Charge inside a Sphere Consider the total electric flux $\oint \mathbf{E} \cdot d\boldsymbol{\sigma}$ out of a sphere of radius R around the origin surrounding n charges e_j located at the points $\mathbf{r}_j$ with $r_j < R$ (i.e., inside the sphere). The electric field strength $\mathbf{E} = -\boldsymbol{\nabla}\varphi(\mathbf{r})$, where the potential

$$\varphi = \sum_{j=1}^{n} \frac{e_j}{|\mathbf{r} - \mathbf{r}_j|} = \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d^3r'$$

is the sum of the Coulomb potentials generated by each charge and the total charge density is $\rho(\mathbf{r}) = \sum_j e_j \delta(\mathbf{r} - \mathbf{r}_j)$. The delta function is used here as an abbreviation of a pointlike density. Now we use Gauss's theorem for

$$\oint \mathbf{E} \cdot d\boldsymbol{\sigma} = -\oint \boldsymbol{\nabla}\varphi \cdot d\boldsymbol{\sigma} = -\int \boldsymbol{\nabla}^2 \varphi d\tau = \int \frac{\rho(\mathbf{r})}{\varepsilon_0} d\tau = \frac{\sum_j e_j}{\varepsilon_0}$$

in conjunction with the differential form of Gauss's law $\boldsymbol{\nabla} \cdot \mathbf{E} = -\rho/\varepsilon_0$ and $\sum_j e_j \int \delta(\mathbf{r} - \mathbf{r}_j) d\tau = \sum_j e_j$. ■

The integral property [Eq. (1.151)] is useful in cases in which the argument of the delta function is a function $g(x)$ with **simple zeros** on the real axis, which leads to the rules

$$\delta(ax) = \frac{1}{a}\delta(x), \quad a > 0, \tag{1.161}$$

$$\delta(g(x)) = \sum_{\substack{a, \\ g(a)=0, \\ g'(a)\neq 0}} \frac{\delta(x-a)}{|g'(a)|}. \tag{1.162}$$

To obtain Eq. (1.161) we change the integration variable in

$$\int_{-\infty}^{\infty} f(x)\delta(ax)dx = \frac{1}{a}\int_{-\infty}^{\infty} f\left(\frac{y}{a}\right)\delta(y)dy = \frac{1}{a}f(0)$$

and apply Eq. (1.151). To prove Eq. (1.162) , we decompose the integral

$$\int_{-\infty}^{\infty} f(x)\delta(g(x))dx = \sum_a \int_{a-\varepsilon}^{a+\varepsilon} f(x)\delta((x-a)g'(a))dx \tag{1.163}$$

into a sum of integrals over small intervals containing the first-order zeros of $g(x)$. In these intervals, $g(x) \approx g(a) + (x-a)g'(a) = (x-a)g'(a)$. Using Eq. (1.161) on the right-hand side of Eq. (1.163), we obtain the integral of Eq. (1.162).

EXAMPLE 1.14.3

Evaluate $I \equiv \int_{-\infty}^{\infty} f(x)\delta(x^2-2)dx$ Because the zeros of the argument of the delta function, $x^2 = 2$, are $x = \pm\sqrt{2}$, we can write the integral as a sum of two contributions:

$$\begin{aligned} I &= \int_{\sqrt{2}-\epsilon}^{\sqrt{2}+\epsilon} \delta(x-\sqrt{2}) \frac{f(x)dx}{\frac{d(x^2-2)}{dx}|_{x=\sqrt{2}}} dx + \int_{-\sqrt{2}-\epsilon}^{-\sqrt{2}+\epsilon} \delta(x+\sqrt{2}) \frac{f(x)dx}{\frac{d(x^2-2)}{dx}|_{x=-\sqrt{2}}} \\ &= \int_{\sqrt{2}-\epsilon}^{\sqrt{2}+\epsilon} \delta(x-\sqrt{2}) \frac{f(x)dx}{2\sqrt{2}} + \int_{-\sqrt{2}-\epsilon}^{-\sqrt{2}+\epsilon} \delta(x+\sqrt{2}) \frac{f(x)dx}{2\sqrt{2}} \\ &= \frac{f(\sqrt{2}) + f(-\sqrt{2})}{2\sqrt{2}}. \end{aligned}$$ ■

This example is good training for the following one.

EXAMPLE 1.14.4

Phase Space In the scattering theory of relativistic particles using Feynman diagrams, we encounter the following integral over energy of the scattered particle (we set the velocity of light $c = 1$):

$$\begin{aligned} \int d^4p\,\delta(p^2 - m^2) f(p) &\equiv \int d^3p \int dp_0 \delta\left(p_0^2 - \mathbf{p}^2 - m^2\right) f(p) \\ &= \int_{E>0} \frac{d^3p f(E, \mathbf{p})}{2\sqrt{m^2 + \mathbf{p}^2}} - \int_{E<0} \frac{d^3p f(E, \mathbf{p})}{2\sqrt{m^2 + \mathbf{p}^2}}, \end{aligned}$$

where we have used Eq. (1.162) at the zeros $E = \pm\sqrt{m^2 + \mathbf{p}^2}$ of the argument of the delta function. The physical meaning of $\delta(p^2 - m^2)$ is that the particle of mass m and four-momentum $p^\mu = (p_0, \mathbf{p})$ is on its mass shell because $p^2 = m^2$ is equivalent to $E = \pm\sqrt{m^2 + \mathbf{p}^2}$. Thus, the on-mass-shell volume element in momentum space is the Lorentz invariant $\frac{d^3p}{2E}$, in contrast to the nonrelativistic d^3p of momentum space. The fact that a negative energy occurs is a peculiarity of relativistic kinematics that is related to the antiparticle. ■

Using integration by parts we can also **define the derivative** $\delta'(x)$ of the Dirac delta function by the relation

$$\int_{-\infty}^{\infty} f(x)\delta'(x - x')\,dx = -\int_{-\infty}^{\infty} f'(x)\delta(x - x')\,dx = -f'(x'). \qquad (1.164)$$

It should be understood that our Dirac delta function has significance only as part of an integrand. Thus, the Dirac delta function is often regarded as a linear operator: $\delta(x - x_0)$ operates on $f(x)$ and yields $f(x_0)$:

$$\mathcal{L}(x_0) f(x) \equiv \int_{-\infty}^{\infty} \delta(x - x_0) f(x)\,dx = f(x_0). \qquad (1.165)$$

It may also be classified as a linear mapping or simply as a generalized function. Shifting our singularity to the point $x = x'$, we write the Dirac delta function as $\delta(x - x')$. Equation (1.151) becomes

$$\int_{-\infty}^{\infty} f(x)\delta(x - x')\,dx = f(x'). \tag{1.166}$$

As a description of a singularity at $x = x'$, the Dirac delta function may be written as $\delta(x - x')$ or as $\delta(x' - x)$. Expanding to three dimensions and using spherical polar coordinates, we obtain

$$\begin{aligned} f(0) &= \int_0^{2\pi}\int_0^{\pi}\int_0^{\infty} f(\mathbf{r})\delta(\mathbf{r})\,r^2\,dr\sin\theta\,d\theta\,d\varphi \\ &= \iiint_{-\infty}^{\infty} f(x, y, z)\delta(x)\,\delta(y)\,\delta(z)\,dx\,dy\,dz, \\ &\int_0^{\infty}\frac{\delta(r)}{r^2}r^2 dr\int_{-1}^{1}\delta(\cos\theta)\,d\cos\theta\int_0^{2\pi}\delta(\varphi)\,d\varphi = 1, \end{aligned} \tag{1.167}$$

where each one-dimensional integral is equal to unity. This corresponds to a singularity (or source) at the origin. Again, if our source is at $\mathbf{r} = \mathbf{r}_1$, Eq. (1.167) generalizes to

$$\iiint f(\mathbf{r}_2)\delta(\mathbf{r}_2 - \mathbf{r}_1)\,r_2^2 dr_2\sin\theta_2\,d\theta_2\,d\varphi_2 = f(\mathbf{r}_1), \tag{1.168}$$

where

$$\int_0^{\infty}\frac{\delta(r_2 - r_1)}{r_2^2}r_2^2 dr_2\int_{-1}^{1}\delta(\cos\theta_2 - \cos\theta_1)d\cos\theta_2\int_0^{2\pi}\delta(\varphi_2 - \varphi_1)d\varphi_2 = 1.$$

SUMMARY

We use $\delta(x)$ frequently and call it the Dirac delta function—for historical reasons.[19] Remember that it is not really a function. It is essentially a shorthand notation, defined implicitly as the limit of integrals in a sequence, $\delta_n(x)$, according to Eq. (1.160).

Biographical Data

Dirac, Paul Adrien Maurice. Dirac, an English physicist, was born in Bristol in 1902 and died in Bristol in 1984. He obtained a degree in electrical engineering at Bristol and obtained his Ph.D. in mathematical physics in 1926 at Cambridge. By 1932, he was Lucasian professor, like Stokes, the chair Newton once held. In the 1920s, he advanced quantum mechanics, became one of the founders of quantum field theory, and, in 1928, discovered his relativistic equation for the electron that predicted antiparticles for which he was awarded the Nobel prize in 1933.

---

[19] Dirac introduced the delta function to quantum mechanics. Actually, the delta function can be traced back to Kirchhoff, 1882. For further details, see M. Jammer (1966). *The Conceptual Development of Quantum Mechanics*, p. 301. McGraw-Hill, New York.

A startling consequence of Theorem 6.2 is that in hyperbolic geometry a segment can be determined with the aid of an angle; for example, an angle of an equilateral triangle determines the length of a side uniquely. This is sometimes stated more dramatically by saying that hyperbolic geometry has an *absolute unit of length* (see Gauss' letter to Taurinus, quoted earlier in this chapter). If the geometry of the physical universe were hyperbolic, it would no longer be necessary to keep a unit of length carefully guarded in the Bureau of Standards (the same is true for elliptic geometry).

PARALLELS THAT ADMIT A COMMON PERPENDICULAR

In Chapter 5, commenting on the flaw in Proclus' attempted proof of the parallel postulate, I remarked that it was presumptuous to assume that parallel lines looked like railroad tracks, that is, that they were everywhere equidistant from each other. Let us now make this remark more precise. Given lines l and l' and points A, B, C, . . . on l. Drop perpendiculars AA′, BB′, CC′, . . . from these points to l'. We will say that points A, B, C, . . . are *equidistant* from l' if all these perpendicular segments are congruent to one another (Figure 6.5).

THEOREM 6.3. In hyperbolic geometry if l and l' are any distinct parallel lines, then any set of points on l equidistant from l' has at most two points in it.

Proof:
Assume on the contrary there is a set of three points A, B, and C on l equidistant from l'. Then quadrilaterals □A′B′BA, □A′C′CA,

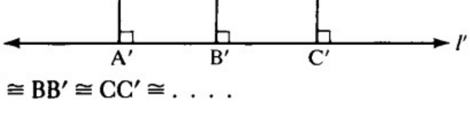

FIGURE 6.5 AA′ ≅ BB′ ≅ CC′ ≅ . . . .

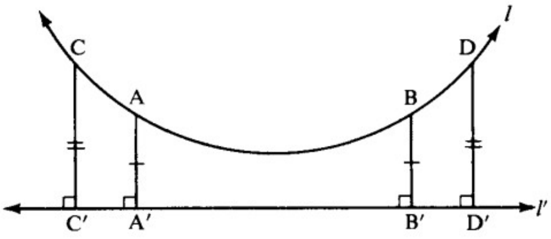

FIGURE 6.6

and □B′C′CB are Saccheri quadrilaterals (the base angles are right angles and the sides are congruent). In Exercise 1, Chapter 5, you showed that the summit angles of a Saccheri quadrilateral are congruent. Thus, ∢A′AB ≅ ∢B′BA, ∢A′AC ≅ ∢C′CA, and ∢B′BC ≅ ∢C′CB. By transitivity (Axiom C-5), it follows that the supplementary angles ∢B′BA and ∢B′BC are congruent to each other; hence, by definition, they are right angles. Therefore, these Saccheri quadrilaterals are all rectangles. But rectangles do not exist in hyperbolic geometry (Lemma 6.1). This contradiction shows that A, B, and C cannot be equidistant from *l*′. ■

The theorem states that *at most* two points at a time on *l* can be equidistant from *l*′. It allows the possibility that there are pairs of points (A, B), (C, D), . . . on *l* such that each pair is equidistant from *l*′—thus, dropping perpendiculars, AA′ ≅ BB′ and CC′ ≅ DD′, but AA′ is not congruent to CC′. A diagram for this might be Figure 6.6, which suggests that the point "in the middle" of *l* is closest to *l*′, with *l* moving away from *l*′ symmetrically on either side of this middle point. We will prove that this is indeed the case (Theorems 6.4 and 6.5 and Exercises 4 and 10).

Note, however, that Theorem 6.3 allows another possibility, that there is no pair of points on *l* equidistant from *l*′! An diagram for this might be Figure 6.7, where the points on *l* are at varying distances from *l*′; *l* moves away from *l*′ in one direction and approaches *l*′ in the other direction without ever meeting it. Thus, different pairs of parallel lines need not resemble each other—some may look like the first diagram, some like the second.

THEOREM 6.4. In hyperbolic geometry if *l* and *l*′ are parallel lines for which there exists a pair of points A and B on *l* equidistant from *l*′, then

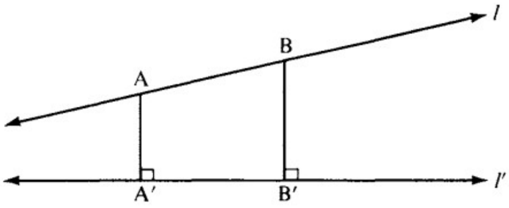

FIGURE 6.7 BB′ > AA′.

l and *l*′ have a common perpendicular segment that is also the shortest segment between *l* and *l*′.

Proof:
Suppose A and B on *l* are equidistant from *l*′. Then □A′B′BA is a Saccheri quadrilateral, where A′ and B′ are the feet on *l*′ of the perpendiculars from A and B. Let M be the midpoint of AB and M′ the midpoint of A′B′ (Proposition 4.3; see Figure 6.8). The theorem will follow from the next lemma. ■

LEMMA 6.2. The segment joining the midpoints of the base and summit of a Saccheri quadrilateral is perpendicular to both the base and the summit, and this segment is shorter than the sides (see Figure 6.8).

Proof:
We know that ∢A ≅ ∢B (Exercise 1, Chapter 5). Hence, ΔA′AM ≅ ΔB′BM (SAS). Therefore, the corresponding sides A′M and B′M are congruent. This implies ΔA′M′M ≅ ΔB′M′M (SSS). Therefore, the corresponding angles ∢A′M′M and ∢B′M′M are congruent. Since these are supplementary angles, they must be right angles, proving MM′ perpendicular to the base

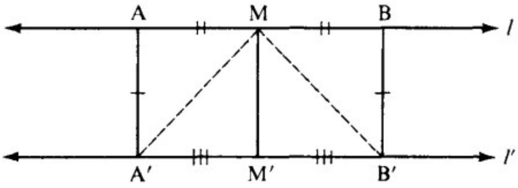

FIGURE 6.8

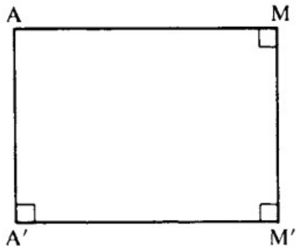

FIGURE 6.9

A′B′. From the two pairs of congruent triangles, we also have ∢A′MM′ ≅ ∢B′MM′ and ∢A′MA ≅ ∢B′MB. Adding the degrees of these angles, we have $(\sphericalangle AMM')^\circ = (\sphericalangle BMM')^\circ$ (Theorem 4.3(3)), i.e., the supplementary angles ∢AMM′ and ∢BMM′ have the same number of degrees. Hence, they are right angles and MM′ is also perpendicular to the summit AB.

Consider next quadrilateral □A′M′MA (Figure 6.9). It has three right angles, so it is what we call a Lambert quadrilateral (Exercise 4, Chapter 5). In hyperbolic geometry the fourth angle must be acute, since rectangles do not exist (Lemma 6.1). You showed in Exercise 4(c), Chapter 5, that AA′ > MM′, i.e., that MM′ is shorter than AA′. The remainder of the proof that MM′ is shorter than any other segment between *l* and *l′* is left for Exercise 3. ■

THEOREM 6.5. In hyperbolic geometry if lines *l* and *l′* have a common perpendicular segment MM′, then they are parallel and MM′ is unique. Moreover, if A and B are any points on *l* such that M is the midpoint of segment AB, then A and B are equidistant from *l′*.

Proof:
The fact that *l* and *l′* are parallel follows from the first corollary to the alternate interior angle theorem (Theorem 4.1). If *l* and *l′* had another common perpendicular segment NN′, then □M′N′NM would be a rectangle, which cannot exist (Lemma 6.1). Suppose now that M is the midpoint of AB. Drop perpendiculars AA′ and BB′ to *l*. We must prove that AA′ ≅ BB′. (See Figure 6.10.) First, ΔAM′M ≅ ΔBM′M (SAS), AM′ ≅ BM′, and ∢AM′M ≅ ∢BM′M. Therefore, $(\sphericalangle A'M'A)^\circ = 90^\circ - (\sphericalangle AM'M)^\circ = 90^\circ -$

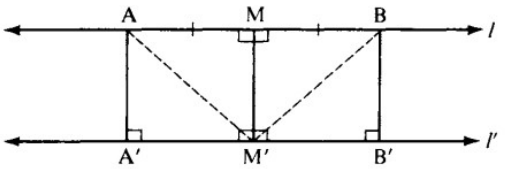

FIGURE 6.10

$(\sphericalangle BM'M)^\circ = (\sphericalangle B'M'B)^\circ$ (by Theorem 4.3) so that $\sphericalangle A'M'A \cong \sphericalangle B'M'B$. Hence, $\triangle AA'M' \cong \triangle BB'M'$ (AAS), so that the corresponding sides AA′ and BB′ are congruent. ■

LIMITING PARALLEL RAYS

Theorems 6.4 and 6.5 and Exercises 4 and 10 give us a good understanding of the first type of parallel lines. We know that such lines actually exist from the usual construction: start with any line l and any point P not on it (Figure 6.11). Drop perpendicular $\overleftrightarrow{PQ}$ to l and let m be the perpendicular through P to $\overleftrightarrow{PQ}$. Then m and l have the common perpendicular segment PQ. Pairs of points on m situated symmetrically about $\overleftrightarrow{PQ}$ are equidistant from l. By the universal hyperbolic theorem, there exist other lines n through P parallel to l. We cannot yet say that any such n is the second type of parallel, for n and l might have a common perpendicular going through a point other than P.

How then do we know that parallels of the second type exist? Here the axioms of continuity come in. The following is the intuitive idea (see Figure 6.12). Consider one ray $\overrightarrow{PS}$ of m, and consider various rays between $\overrightarrow{PS}$ and $\overrightarrow{PQ}$. Some of these rays, such as $\overrightarrow{PR}$, will intersect l; others, such as $\overrightarrow{PY}$, will not. A continuity argument shows that as R recedes endlessly on l from Q, $\overrightarrow{PR}$ will approach a certain limiting ray

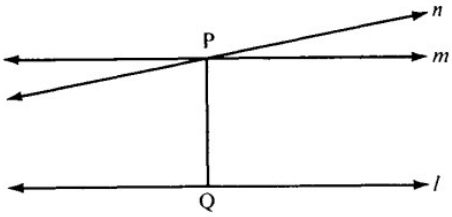

FIGURE 6.11

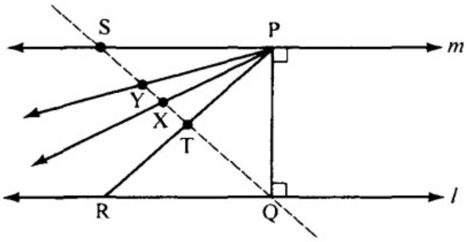

FIGURE 6.12

$\overrightarrow{PX}$ that does *not* meet l. The ray $\overrightarrow{PX}$ is "limiting" in the following precise sense: any ray between $\overrightarrow{PX}$ and $\overrightarrow{PQ}$ intersects l, whereas any other ray $\overrightarrow{PY}$ such that $\overrightarrow{PX}$ is between $\overrightarrow{PY}$ and $\overrightarrow{PQ}$ does not intersect l. The ray $\overrightarrow{PX}$ may be called the *left limiting parallel ray* to l through P. Similarly, there is a *right limiting parallel ray* on the opposite side of $\overrightarrow{PQ}$.

THEOREM 6.6. For every line l and every point P not on l, let Q be the foot of the perpendicular from P to l. Then there are two unique nonopposite rays $\overrightarrow{PX}$ and $\overrightarrow{PX'}$ on opposite sides of $\overleftrightarrow{PQ}$ that do not meet l and have the property that a ray emanating from P meets l if and only if it is between $\overrightarrow{PX}$ and $\overrightarrow{PX'}$. Moreover, these limiting rays are situated symmetrically about $\overleftrightarrow{PQ}$ in the sense that $\sphericalangle XPQ \cong \sphericalangle X'PQ$.

Proof:
To prove rigorously that $\overrightarrow{PX}$ exists, consider the line $\overleftrightarrow{SQ}$ (Figure 6.12). Let Σ_1 be the set of all points T on segment SQ such that $\overrightarrow{PT}$ meets l, together with all points on the ray opposite to $\overrightarrow{QS}$; let Σ_2 be the complement of Σ_1 (so $Q \in \Sigma_1$ and $S \in \Sigma_2$). By the crossbar theorem (Chapter 3), if point T on segment SQ belongs to Σ_1, then the entire segment TQ (in fact, $\overrightarrow{TQ}$) is contained in Σ_1. Hence, (Σ_1, Σ_2) is a Dedekind cut. By Dedekind's axiom (Chapter 3), there is a unique point X on $\overleftrightarrow{SQ}$ such that for P_1 and P_2 on $\overleftrightarrow{SQ}$, $P_1 * X * P_2$ if and only if $X \neq P_1$ or P_2, $P_1 \in \Sigma_1$, and $P_2 \in \Sigma_2$.

By definition of Σ_1 and Σ_2, rays below $\overrightarrow{PX}$ all meet l and rays above $\overrightarrow{PX}$ do not. We claim that $\overrightarrow{PX}$ does not meet l either. Assume on the contrary that $\overrightarrow{PX}$ meets l in a point U (Figure 6.13). Choose any point V on l to the left of U, i.e., $V * U * Q$ (Axiom B-2). Since V and U are on the same side of $\overleftrightarrow{SQ}$ (Exercise 9, Chapter 3), V and P are on opposite sides, so VP meets SQ in a point Y. We have

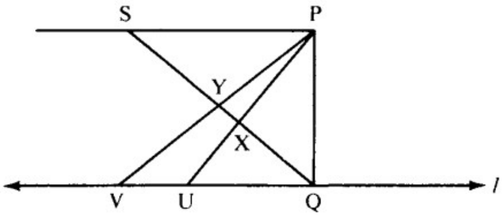

FIGURE 6.13

$Y * X * Q$ (Proposition 3.7), so $Y \in \Sigma_2$, contradicting the fact that $\overrightarrow{PY}$ meets l. It follows that $\overrightarrow{PX}$ is the left limiting parallel ray (we obtain the right limiting parallel ray in a similar manner).

To prove symmetry, assume on the contrary that angles $\sphericalangle XPQ$ and $\sphericalangle X'PQ$ are not congruent, e.g., $(\sphericalangle XPQ)^\circ < (\sphericalangle X'PQ)^\circ$. By Axiom C-4, there is a ray between $\overrightarrow{PX'}$ and $\overrightarrow{PQ}$ that intersects l (by definition of limiting ray) in a point R′ such that $\sphericalangle R'PQ \cong \sphericalangle XPQ$ (Figure 6.14). Let R be the point on the opposite side of $\overleftrightarrow{PQ}$ from R′ such that $R * Q * R'$ and $RQ \cong R'Q$ (Axiom C-1). Then $\Delta RPQ \cong \Delta R'PQ$ (SAS). Hence, $\sphericalangle RPQ \cong \sphericalangle R'PQ$, and by transitivity (Axiom C-5), $\sphericalangle RPQ \cong \sphericalangle XPQ$. But this is impossible, because $\overrightarrow{PR}$ is between $\overrightarrow{PX}$ and $\overrightarrow{PQ}$ (Axiom C-4). ■

Either of the congruent angles $\sphericalangle XPQ$ and $\sphericalangle X'PQ$ is called (by an abuse of language) the *angle of parallelism* at point P with respect to l. Its degree measure is usually denoted $\Pi(PQ)^\circ$. Note that $\Pi(PQ)^\circ < 90^\circ$, for $\Pi(PQ)^\circ = 90^\circ$ would contradict the universal hyperbolic theorem (see Exercise 7(a)). It can be shown that as P varies, $\Pi(PQ)^\circ$ takes on all possible values between 0° and 90° (see Major Exercise 9). One of the greatest discoveries by J. Bolyai and Lobachevsky is their formula for this number of degrees (see

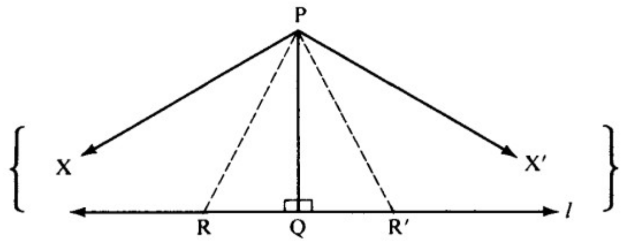

FIGURE 6.14

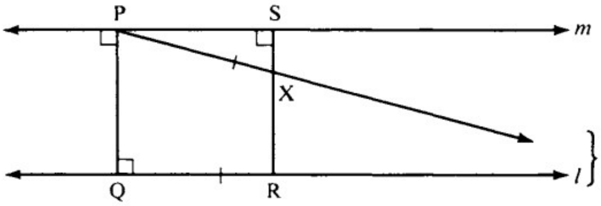

FIGURE 6.15

Theorem 10.2 in Chapter 10). A *natural unit segment* OI in hyperbolic geometry is any segment OI such that $\Pi(OI)^\circ = 45^\circ$. Major Exercise 5 shows that all such segments are congruent to each other.

We have proved the existence of limiting parallel rays by a continuity argument conforming to today's standards of rigor. Gauss, J. Bolyai, and Lobachevsky took this existence for granted, but J. Bolyai discovered a simple *straightedge-and-compass construction* for the limiting rays. Let Q be the foot of the perpendicular from P to *l*, *m* the line through P perpendicular to $\overleftrightarrow{PQ}$, R any point on *l* different from Q, and S the foot of the perpendicular from R to *m* (Figure 6.15). Then PR > QR (Exercise 3) and PS < QR (Exercise 4(c), Chapter 5, on Lambert quadrilaterals). By the elementary continuity principle, a compass with center P and radius congruent to QR will intersect segment SR in a unique point X between S and R. It can be proved that $\overrightarrow{PX}$ is the right limiting parallel ray to *l* through P! (The proof is complicated. See p. 269 in Chapter 7, Project 4 in this chapter, or Theorem 10.9, Chapter 10.)

CLASSIFICATION OF PARALLELS

We have discussed two types of parallels to a given *l*. The first type consists of parallels *m* such that *l* and *m* have a common perpendicular; *m* diverges from *l* on both sides of the common perpendicular. The second type consists of parallels that approach *l* asymptotically in one direction (i.e., they contain a limiting parallel ray in that direction) and which diverge from *l* in the other direction. If *m* is the second type of parallel, Exercises 7 and 8 show that *l* and *m* do not have a common perpendicular. We have implied that these two are the only types of parallels, and this is the content of the next theorem.

THEOREM 6.7. Given m parallel to l such that m does not contain a limiting parallel ray to l in either direction. Then there exists a common perpendicular to m and l (which is unique by Theorem 6.5).

This theorem is proved by Borsuk and Szmielew (1960, p. 291) by a continuity argument, but their proof gives you no idea of how to actually find the common perpendicular. There is an easy way to find it in the Klein and Poincaré models, discussed in the next chapter. Hilbert gave a direct construction, which we will sketch. (Project 1 gives another.)

Proof:
Hilbert's idea is to find two points H and K on l that are equidistant from m, for once these are found, the perpendicular bisector of segment HK is also perpendicular to m (see Lemma 6.2). Choose any two points A and B on l and suppose that the perpendicular segment AA′ from A to m is longer than the perpendicular segment BB′ from B to m. (See Figure 6.16.) Let E be the point between A′ and A such that A′E ≅ B′B. On the same side of $\overleftrightarrow{AA'}$ as B, let $\overrightarrow{EF}$ be the unique ray such that ∢A′EF ≅ ∢B′BG, where A * B * G. The key point that will be proved in Major Exercises 2–6 is that $\overrightarrow{EF}$ intersects $\overrightarrow{AG}$ in a point H. Let K be the unique point on $\overrightarrow{BG}$ such that EH ≅ BK. Drop perpendiculars $\overleftrightarrow{HH'}$ and $\overleftrightarrow{KK'}$ to m. The upshot of these constructions is that □EHH′A′ is congruent to □BKK′B′ (just divide them into triangles). Hence, the corresponding sides HH′ and KK′ are congruent, so that the points H and K on l are equidistant from m, as required. ■

To sum up, given a point P not on l, there exist exactly two limiting parallel rays to l through P, one in each direction. There are infinitely many lines through P that do not enter the region between the limiting

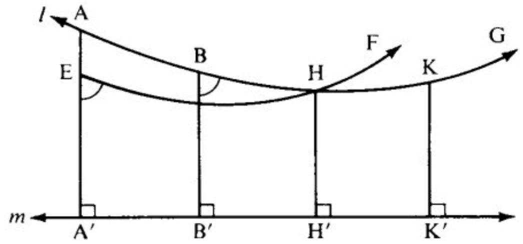

FIGURE 6.16

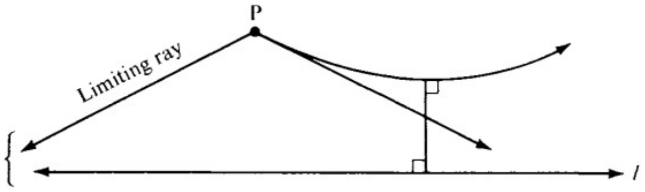

FIGURE 6.17

rays and l. Each such line is divergently parallel to l and admits a unique common perpendicular with l (for one of these lines the common perpendicular will go through P, but for all the rest the common perpendicular will pass through other points).

A Note on Terminology. In most books on hyperbolic geometry the word "parallel" is used only for lines that contain limiting parallel rays in our sense. The other lines, which admit a common perpendicular, have various names in the literature: "nonintersecting," "ultraparallel," "hyperparallel," and "superparallel." We will continue to use the word "parallel" to mean "nonintersecting." A parallel to l that contains a limiting parallel ray to l will be called an *asymptotic parallel,* and a parallel to l that admits a common perpendicular to l will be called a *divergently parallel line.* Rays that are limiting parallel will be denoted by a brace in diagrams (see Figure 6.17).

STRANGE NEW UNIVERSE?

In this chapter we have only begun to investigate the "strange new universe" of hyperbolic geometry. You can develop more of this geometry by doing the exercises, reading Chapter 10, and examining works in the bibliography at the end of the book. You will encounter new entities such as asymptotic triangles, ideal and ultra-ideal points, equidistant curves, horocycles, and pseudospheres.

If you consider this geometry too "far out" to pursue, you are in for a surprise. We will see in the next chapter that if the undefined terms of hyperbolic geometry are suitably interpreted, hyperbolic geometry can be considered a part of Euclidean geometry!

Meanwhile, notice how we have deepened our understanding of the role of the parallel postulate *P* in Euclidean geometry. Any statement *S* in the language of our geometry that is a theorem in Euclidean geometry ($P \Rightarrow S$) and whose negation is a theorem in hyperbolic geometry ($\sim P \Rightarrow \sim S$) is equivalent (in neutral geometry) to the parallel postulate (by Logic Rule 9(c)). For example, by Exercise 14, Chapter 5, "The angle sum of every triangle is 180°" is such a statement. By Exercise 12 in this chapter, "Every triangle has a circumscribed circle" is another such statement. By Theorem 5.1, "Every point interior to an acute angle lies on a line intersecting both sides of the angle in two distinct points" is a third such statement. I leave the enjoyment of providing a long list of such statements to you (Exercise 15). I urge your instructor to give a prize to the student(s) with the longest list.

REVIEW EXERCISE

Which of the following statements are correct?

(1) The negation of Hilbert's parallel postulate states that for every line *l* and every point P not on *l* there exist at least two lines through P parallel to *l*.

(2) It is a theorem in neutral geometry that if lines *l* and *m* meet on a given side of a transversal *t*, then the sum of the degrees of the interior angles on that given side of *t* is less than 180°.

(3) Gauss began working on non-Euclidean geometry when he was 15 years old.

(4) The philosopher Kant taught that our minds could not conceive of any geometry other than Euclidean geometry.

(5) The first mathematician to publish an account of hyperbolic geometry was the Russian Lobachevsky.

(6) The crossbar theorem asserts that a ray emanating from a vertex A of $\triangle ABC$ and interior to $\sphericalangle A$ must intersect the opposite side BC of the triangle.

(7) It is a theorem in hyperbolic geometry that for any segment AB there exists a square having AB as one of its sides.

(8) Every Saccheri quadrilateral is a convex quadrilateral.

(9) In hyperbolic geometry if $\triangle ABC$ and $\triangle DEF$ are equilateral triangles and $\sphericalangle A \cong \sphericalangle D$, then the triangles are congruent.

CHAPTER 7

INDEPENDENCE OF THE PARALLEL POSTULATE

> All my efforts to discover a contradiction, an inconsistency, in this non-Euclidean geometry have been without success. . . .
>
> C. F. GAUSS

CONSISTENCY OF HYPERBOLIC GEOMETRY

In the previous chapter you were introduced to hyperbolic geometry and presented with some theorems that must seem very strange to someone accustomed to Euclidean geometry. Even though you may admit that the proofs of these theorems are correct, given our assumptions, you may feel that the basic assumption of hyperbolic geometry — the hyperbolic axiom — is a false assumption. Let's examine what might be meant by saying it's false.

Suppose I assume that when I drop some object, say, a stone, it will "fall" upward. I can go out and drop rocks and, unless I have rocks in my head, I will discover that my assumption was false.

Now what sort of experiment could I perform to show that the hyperbolic assumption is false, or, equivalently, to show that its negation, the Euclidean parallel postulate, is true? First of all, I would have to understand what this statement means. In the above example I understood very well the meaning of "stone" and what it means to "drop" one, so I could act upon this understanding. But what does it mean that *l* is a "line," that P is a "point" not "on" *l*, or that there is a "unique parallel" to *l* through P? I might represent "points" and

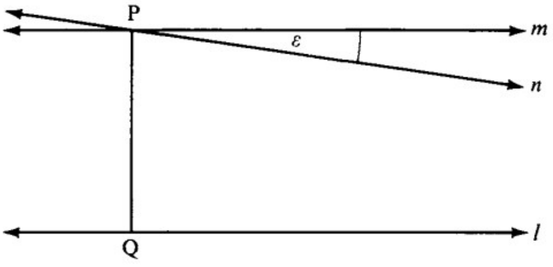

FIGURE 7.1

"lines" with paper, pencil, and straightedge. Suppose I draw $\overleftrightarrow{PQ}$ perpendicular to *l* and *m* through P perpendicular to $\overleftrightarrow{PQ}$, and then draw a line *n* through P, making a very small angle of $\epsilon°$ with *m*. Using Euclidean trigonometry, I can calculate exactly how far out on *n* I would have to go to get to the point where *n* is supposed to intersect *l*, but if ϵ is small enough, that point might be millions of miles away. Thus, I could not physically perform the experiment to prove that the hyperbolic axiom is false.

But is geometry about lines that we can draw? Applied geometry (engineering) is; but pure geometry is about ideal lines, which are concepts, not objects. The only experiments we can perform on these ideal lines are thought-experiments. So the question should be: Can we *conceive* of a non-Euclidean geometry? Kant said no, that any geometry other than Euclidean is inconceivable. At the time, of course, no one had yet conceived of a different geometry. It is in this sense that Gauss, J. Bolyai, and Lobachevsky created a "new universe."

Other questions can be raised. Mathematicians reject many of their own ideas because they either lead to contradictions or do not lead anywhere, i.e., do not prove fruitful, useful, or interesting. Does the hyperbolic axiom lead to a contradiction? Saccheri thought it would, and tried to prove the parallel postulate that way. Is hyperbolic geometry fruitful, useful, or interesting?

Let us postpone this question and take up the former: Is hyperbolic geometry *consistent?* Nowadays we refer to this as a question in *metamathematics,* i.e., a question outside of a mathematical system about the system itself. The question is not about lines or points or other geometric entities; it is a question about the *whole system* of hyperbolic geometry.

If hyperbolic geometry were inconsistent, an ordinary mathematical argument could derive a contradiction. Saccheri tried to do this and failed. Could it be that he wasn't clever enough, that someday some genius will find a contradiction?

On the other hand, can it be proved that hyperbolic geometry is *consistent*—can it be proved that there is no possible way to derive a contradiction?

We might ask the same question about Euclidean geometry—how do we *know* it is consistent? Of course, this was never a burning question before the discovery of non-Euclidean geometry simply because everyone *believed* Euclidean geometry to be consistent. Remarkably enough, if we make this belief an explicit assumption (albeit a metamathematical assumption), it is possible to give a proof that hyperbolic geometry is consistent. Let us state this possibility as a theorem:

METAMATHEMATICAL THEOREM 1. If Euclidean geometry is consistent, then so is hyperbolic geometry.

Granting this result for the moment, we get the following important corollary.

COROLLARY. If Euclidean geometry is consistent, then no proof or disproof of the parallel postulate from the rest of Hilbert's postulates will ever be found, i.e., the parallel postulate is independent of the other postulates.

> To prove the corollary, assume on the contrary that a proof of the parallel postulate exists. Then hyperbolic geometry would be inconsistent, since the hyperbolic axiom contradicts a proved result. But Metamathematical Theorem 1 asserts that hyperbolic geometry is consistent relative to Euclidean geometry. This contradiction proves that no proof of the parallel postulate exists (RAA). The hypothesis that Euclidean geometry is consistent ensures that no *dis*proof exists either. ■

Thus, 2000 years of efforts to prove Euclid V were in vain. There is no more hope of proving it than there is of finding a method for trisecting every angle using straightedge and compass alone.

Of course, when we say this, we are *assuming* the consistency of the venerable Euclidean geometry. Had Saccheri, Legendre, F. Bolyai, or any of the dozens of other scholars succeeded in proving Euclid V from the other axioms, with the noble intention of making Euclidean geometry more secure and elegant, they would have instead completely destroyed Euclidean geometry as a consistent body of thought! (I urge you, dear reader, to go over the preceding statements very carefully to make sure you have understood them. If you have not understood, you have missed the main point of this book.)

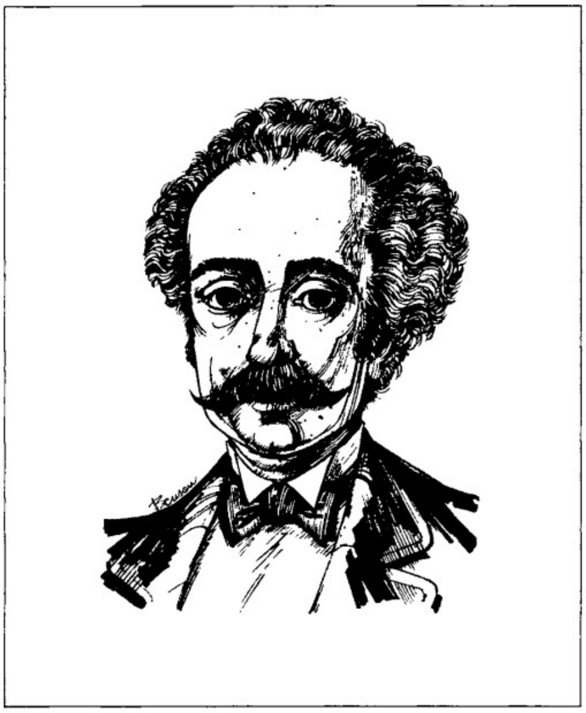
In the form given here, Metamathematical Theorem 1 is due to Eugenio Beltrami (1835–1900); a different proof was later given by Felix Klein (1849–1925).[1] Beltrami proved the relative consistency of hyperbolic geometry in 1868 using differential geometry (see The Pseudosphere, Chapter 10). Klein recognized that projective geometry could be used to give another proof. In 1871 he applied the method Arthur Cayley used (in 1859) to express distance and angle measure by projective coordinates.

To prove Metamathematical Theorem 1, we have to again ask ourselves, What is a "line" in hyperbolic geometry—in fact, what is the hyperbolic plane? The honest answer is that we don't know; it is just an abstraction. A hyperbolic "line" is an undefined term describing an abstract concept that resembles the concept of a Euclidean line except for its parallelism properties. Then how shall we visualize hyperbolic geometry? In mathematics, as in any other field of research, posing the right question is just as important as finding answers.

The question of "visualizing" means finding Euclidean objects that represent hyperbolic objects. This means finding a Euclidean *model* for hyperbolic geometry. In Chapter 2 we discussed the idea of models for an axiom system; there we showed that the Euclidean parallel postulate is independent of the axioms for incidence geometry by exhibiting three-point and five-point models of incidence geometry that are not Euclidean. Here we want to know whether the parallel postulate is independent of a much *larger* system of axioms, namely,

---

[1] Beltrami made important contributions to differential geometry. Klein was a master of many branches of mathematics and an influential teacher. His book on the history of nineteenth-century mathematics shows how familiar he was with all aspects of the subject. Klein's famous inaugural address in 1872, his *Erlanger Programme*, made the study of groups of transformations and their invariants the key to geometry (see Chapter 9).



Eugenio Beltrami

neutral geometry. We can show that it is, and by the same method—by exhibiting models for hyperbolic geometry.[2]

THE BELTRAMI-KLEIN MODEL

For brevity, we will refer to this first model (the Beltrami-Klein model) as the "Klein model." We fix once and for all a circle γ in the Euclidean plane (which Cayley referred to as "the absolute"). If O is

---

[2] Unlike the situation for incidence geometry, we cannot construct a model for neutral geometry in which the elliptic parallel property holds, because it is a theorem in neutral geometry that parallel lines exist (see Corollary 2 to Theorem 4.1). If you worked through Major Exercise 13, Chapter 6, you will easily understand the motivation for the Beltrami-Klein model. It is the projective completion of the hyperbolic plane!

Felix Klein

the center of γ and OR is a radius, the *interior* of γ by definition consists of all points X such that $OX < OR$ (see Figure 7.2). In Klein's model the points in the interior of γ represent the points of the hyperbolic plane.

Recall that a chord of γ is a segment AB joining two points A and B on γ. We wish to consider the segment without its endpoints, which we will call an *open chord* and denote by A)(B. In Klein's model the open chords of γ represent the lines of the hyperbolic plane. The relation "lies on" is represented in the usual sense: P lies on A)(B means that P lies on the Euclidean line $\overleftrightarrow{AB}$ and P is between A and B. The hyperbolic relation "between" is represented by the usual Euclidean relation "between." This much is easy. The representation of "congruence" is much more complicated, and we will discuss it later in this chapter (The Projective Nature of the Beltrami-Klein Model).

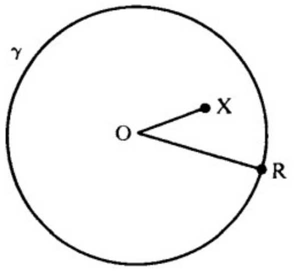


FIGURE 7.2

It is immediately clear from Figure 7.3 that the hyperbolic axiom holds in this representation.

Here the two open chords *m* and *n* through P are both parallel to the open chord *l*—for what does "parallel" mean in this representation? The definition of "parallel" states that two lines are parallel if they have no point in common. In Klein's representation this becomes: two open chords are parallel if they have no point in common (in the definition of "parallel," replace the word "line" by "open chord"). The fact that the three chords, when extended, may meet outside the circle γ is irrelevant—points outside of γ do not represent points of the hyperbolic plane. So let us summarize the Beltrami-Klein proof of the relative consistency of hyperbolic geometry as follows:

First, a glossary is set up to "translate" the five undefined terms ("point," "line," "lies on," "between," and "congruent") into their interpretations in the Euclidean model (we have done this for the first four terms). All the defined terms are then interpreted by "translating" all occurrences of undefined terms. For instance, the defined term "parallel" was interpreted by replacing every occurrence of the

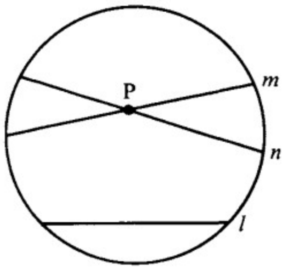

FIGURE 7.3

word "line" in the definition by "open chord." Once all the defined terms have been interpreted, we have to interpret the axioms of the system. Incidence Axiom 1, for example, has the following interpretation in the Klein model:

INCIDENCE AXIOM 1 (Klein). Given any two distinct points A and B in the interior of circle γ. There exists a unique open chord l of γ such that A and B both lie on l.

We must prove that this is a theorem in Euclidean geometry (and similarly, prove the interpretations of all the other axioms). Once all the interpreted axioms have been proved to be theorems in Euclidean geometry, any proof of a contradiction within hyperbolic geometry could be translated by our glossary into a proof of a contradiction in Euclidean geometry. From our assumption that Euclidean geometry is consistent, it follows that no such proof exists. Thus, if Euclidean geometry is consistent, so is hyperbolic geometry.

We must now backtrack and prove that the interpretations of the axioms of hyperbolic geometry in the Klein model are theorems in Euclidean geometry. Let us prove Axiom I-1 (Klein) stated above:

Proof
Given A and B interior to γ. Let $\overleftrightarrow{AB}$ be the Euclidean line through them (see Figure 7.4). This line intersects γ in two distinct points C and D. Then A and B lie on the open chord C)(D, and, by Axiom I-1 for Euclidean geometry, this is the only open chord on which they both lie. ■

In the second step of the proof we used a theorem from Euclidean geometry that states that a line passing through the interior of a circle

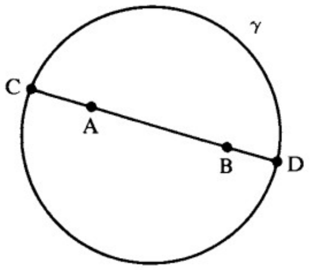

FIGURE 7.4

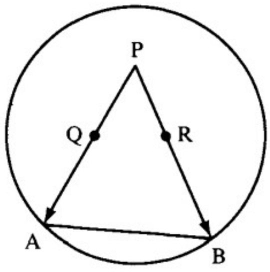

FIGURE 7.5 Limiting parallel rays.

intersects the circle in two distinct points. This can be proved from the circular continuity principle (see Major Exercise 1, Chapter 4). Verifications of the interpretations of the other incidence axioms, the betweenness axioms, and Dedekind's axiom are left as exercises; the congruence axioms are verified later in this chapter.

One nice aspect of the Klein model is that it is easy to visualize the limiting parallel rays (see Figure 7.5). Let P be a point interior to γ and not on the open chord A)(B. A and B are points on the circle and therefore do not represent points in the hyperbolic plane; they are said to represent *ideal points* and are called the *ends* of the hyperbolic line represented by A)(B (see Note 2 following Major Exercise 3, Chapter 6). Then the limiting parallel rays to A)(B from P are represented by the segments PA and PB with the endpoints A and B omitted. It is clear that any ray between these limiting parallel rays intersects the open chord A)(B, whereas all other rays emanating from P do not. The symmetry and transitivity of limiting parallelism (which, as you saw in Major Exercises 2 and 3, Chapter 6, were tricky to prove) are utterly obvious in the Klein model, as is the fact that every angle has a *line of enclosure* (given $\sphericalangle$QPR, if A is the end of $\overrightarrow{PQ}$ and B is the end of $\overrightarrow{PR}$, then A)(B is the line of enclosure of $\sphericalangle$QPR—see Major Exercise 8, Chapter 6).

Let us conclude this section by considering the interpretation in the Klein model of "congruence," the subtlest part of the model. One method of interpretation is to use a system of numerical measurement of angle degrees and segment lengths. Two angles would then be interpreted as congruent if they had the same number of degrees, and two segments would be interpreted as congruent if they had the same length (compare Theorem 4.3). The catch is that Euclidean methods of measuring degrees and lengths cannot be used. If we use Euclidean length, for example, then every line (i.e., open chord) would have a finite length less than or equal to the length of a diameter of γ. This would invalidate the interpretations of Axioms B-2 and C-1, which ensure that lines are infinitely long.

We will further discuss the matter in this chapter (in the sections Perpendicularity in the Beltrami-Klein Model and The Projective Nature of the Beltrami-Klein Model), but first let's consider the Poincaré models, in which congruence of angles is easier to describe.

THE POINCARÉ MODELS

A disk model due to Henri Poincaré (1854–1912)[3] also represents points of the hyperbolic plane by the points *interior* to a Euclidean circle γ, but lines are represented differently. First, all open chords that pass through the center O of γ (i.e., all *open diameters* l of γ) represent lines. The other lines are represented by *open arcs of circles orthogonal to* γ. More precisely, let δ be a circle orthogonal to γ (at each point of intersection of γ and δ the radii of γ and δ through that point are perpendicular). Then intersecting δ with the interior of γ gives an open arc m, which by definition represents a hyperbolic line in the Poincaré model. So we will call *Poincaré line,* or "P-line," either an open diameter l of γ or an open circular arc m orthogonal to γ (see Figure 7.6).

A point interior to γ "lies on" a Poincaré line if it lies on it in the Euclidean sense. Similarly, "between" has its usual Euclidean interpretation (for A, B, and C on an open arc coming from an orthogonal circle δ with center P, B is *between* A and C if $\overrightarrow{PB}$ is between $\overrightarrow{PA}$ and $\overrightarrow{PC}$).

The interpretation of *congruence for segments* in the Poincaré model is complicated, being based on a way of measuring length that is different from the usual Euclidean way, just as in the Klein model (see

---

[3] Poincaré was the cousin of the president of France. Like Gauss, Poincaré made profound discoveries in many branches of mathematics and physics; he even started a new branch of mathematics, algebraic topology. He used his models of hyperbolic geometry to discover new theorems about automorphic functions of a complex variable. Poincaré is also important as a philosopher of science (see Chapter 8).

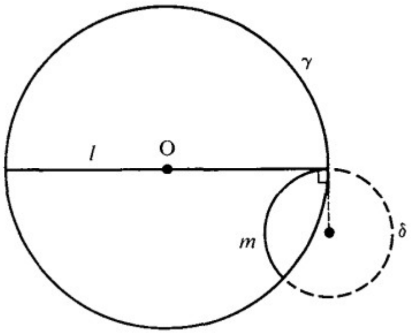

FIGURE 7.6

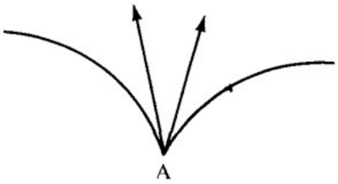

FIGURE 7.7

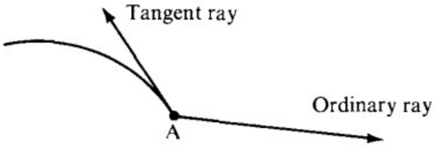

FIGURE 7.8

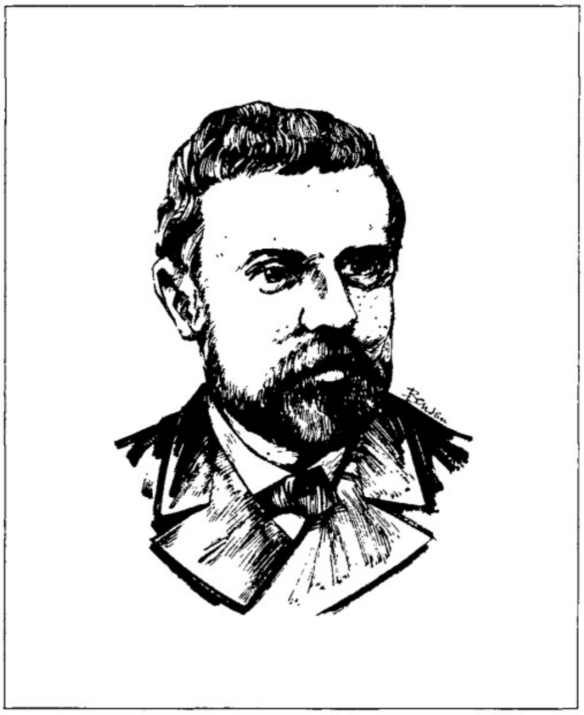
p. 248). *Congruence for angles* has the usual Euclidean meaning, however, and this is the main advantage of the Poincaré model over the Klein model.[4] Specifically, if two directed circular arcs intersect at a point A, the number of degrees in the *angle* they make is by definition the number of degrees in the angle between their tangent rays at A (see Figure 7.7). Or, if one directed circular arc intersects an ordinary ray at A, the number of degrees in the *angle* they make is by definition the number of degrees in the angle between the tangent ray and the ordinary ray at A (see Figure 7.8).

Having interpreted all the undefined terms of hyperbolic geometry in the Poincaré model, we get (by substitution) interpretations of all

---

[4] Technically, we say that the Poincaré model is *conformal*— it represents angles accurately —while the Klein model is not. Another example of a conformal model is Mercator's map of the surface of the earth.



Henri Poincaré

the defined terms. For example, two Poincaré lines are *parallel* if and only if they have no point in common. Then all the axioms of hyperbolic geometry get translated into statements in Euclidean geometry, and it will be shown in the section Inversion in Circles later in this chapter that these interpretations are theorems in Euclidean geometry. Hence, the Poincaré model furnishes another proof that if Euclidean geometry is consistent, so is hyperbolic geometry.

The limiting parallel rays in the Poincaré model are illustrated in Figure 7.9. Here we have chosen l to be an open diameter A)(B; the rays are circular arcs that meet $\overleftrightarrow{AB}$ at A and B and are tangent to this line at those points. You can see how these rays approach l asymptotically as you move out toward the ideal points represented by A and B.

Figure 7.10 illustrates two parallel Poincaré lines with a common perpendicular. The diagram shows how m diverges from l on either side of the common perpendicular PO.

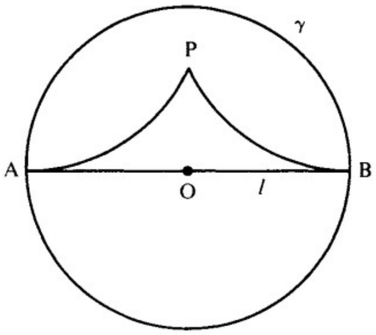


FIGURE 7.9

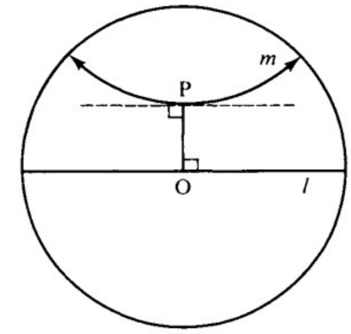

FIGURE 7.10

Figure 7.11 illustrates a Lambert quadrilateral. You can see that the fourth angle is acute. By adding the mirror image of this Lambert quadrilateral we get a diagram illustrating a Saccheri quadrilateral (Figure 7.12).

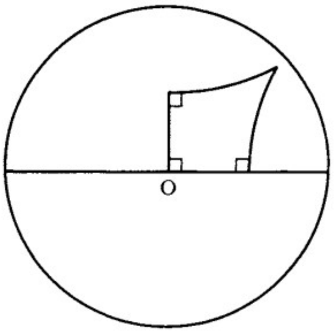

FIGURE 7.11

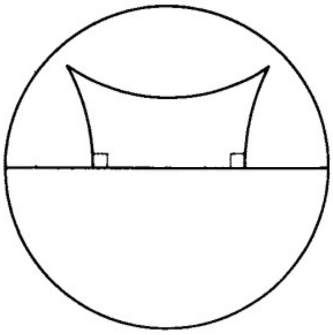

FIGURE 7.12

You may be surprised that we have two different models of hyperbolic geometry, one due to Klein and the other to Poincaré. (There is a third model, also due to Poincaré, soon to be described.) Yet you may have the feeling that these models are not "essentially different." In fact, these models are *isomorphic* in the technical sense that one-to-one correspondences can be set up between the "points" and "lines" in one model and the "points" and "lines" in the other so as to preserve the relations of incidence, betweenness, and congruence. Such isomorphism is illustrated in Figure 7.13. We start with the Klein model and consider, in Euclidean three-space, a sphere of the same radius sitting on the plane of the Klein model and tangent to it at the origin. We project upward orthogonally the entire Klein model onto the lower hemisphere of this sphere; by this projection, the chords in the Klein model become arcs of circles orthogonal to the equator. We then project stereographically from the north pole of the sphere onto the

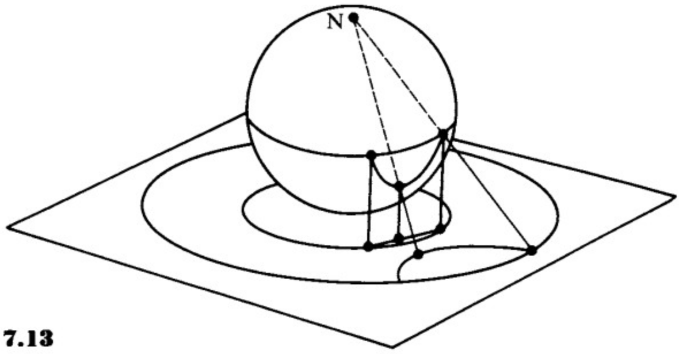

FIGURE 7.13

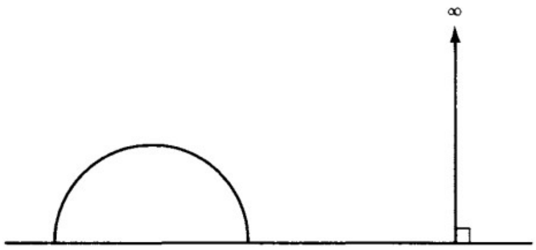

FIGURE 7.14

original plane. The equator of the sphere will project onto a circle larger than the one used in the Klein model, and the lower hemisphere will project stereographically onto the inside of this circle. Under these successive transformations, the chords of the Klein model will be mapped one-to-one onto the diameters and orthogonal arcs of the Poincaré model. In this way the isomorphism of the models may be established.

One can actually prove that *all possible models of hyperbolic geometry are isomorphic to one another,* i.e., that the axioms for hyperbolic geometry are *categorical.* The same is true for Euclidean geometry. The categorical nature of Euclidean geometry is established by introducing Cartesian coordinates into the Euclidean plane. Analogously, the categorical nature of hyperbolic geometry is established by introducing Beltrami coordinates into the hyperbolic plane (for which hyperbolic trigonometry must first be developed).[5]

In the other Poincaré model mentioned here, the points of the hyperbolic plane are represented by the points of one of the Euclidean half-planes determined by a fixed Euclidean line. If we use the Cartesian model for the Euclidean plane, it is customary to make the x axis the fixed line and then to use for our model the upper half-plane consisting of all points (x, y) with $y > 0$. Hyperbolic lines are represented in two ways:

1. As rays emanating from points on the x axis and perpendicular to the x axis;
2. As semicircles in the upper half-plane whose center lies on the x axis (see Figure 7.14).

Incidence and betweenness have the usual Euclidean interpretation.

---

[5] See Chapter 10 as well as Borsuk and Szmielew (1960), Chapter 6.

This model is conformal also (degrees of angles are measured in the Euclidean way). Measurement of lengths will be discussed later.

To establish isomorphism with the previous models, choose a point E on the equator of the sphere in Figure 7.13, and let Π be the plane tangent to the sphere at the point diametrically opposite to E. Stereographic projection from E to Π maps the equator onto a line in Π and the lower hemisphere onto the lower half-plane determined by this line. Notice that the points on this line represent ideal points. However, one ideal point is missing: the point E got lost in the stereographic projection. It is customary to imagine an ideal "point at infinity" ∞ that corresponds to E; it is the common end of all the vertical rays.

PERPENDICULARITY IN THE BELTRAMI-KLEIN MODEL

The Klein model is not conformal. Congruence of angles is interpreted differently from the usual Euclidean way, and will be explained later in this chapter (p. 260). Here we will describe only those angles that are congruent to their supplements, namely, right angles.

Let l and m be open chords of γ. To describe when $l \perp m$ in the Klein model, there are two cases to consider:

Case 1. One of l and m is a diameter. Then $l \perp m$ in the Klein sense if and only if $l \perp m$ in the Euclidean sense. (See Figure 7.15.)

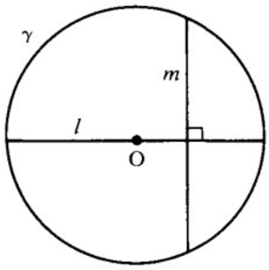

FIGURE 7.15

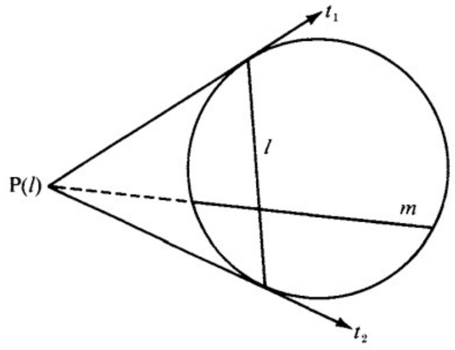

FIGURE 7.16

Case 2. Neither l nor m is a diameter. In this case we associate to l a certain point P(l) outside of γ called the *pole* of l, defined as follows. Let t_1 and t_2 be the tangents to γ at the endpoints of l. Then by definition P(l) is the unique point common to t_1 and t_2 (t_1 and t_2 are not parallel, because l is not a diameter); see Figure 7.16.

It turns out that *l is perpendicular to m in the sense of the Klein model if and only if the Euclidean line extending m passes through the pole of l.*

This description of perpendicularity will be justified later (pp. 260–261). We can use it to see more easily why divergently parallel lines have a common perpendicular — Theorem 6.7. In the hypothesis of Theorem 6.7 we are given two parallel lines that do not contain limiting parallel rays. In the Klein model this means that we are given open chords l and m that do not have a common end. The conclusion of Theorem 6.7 is that l and m have a common perpendicular k. How do we find k? Let's discuss case 2, leaving case 1 as an exercise. By the above description of perpendicularity if k were perpendicular to both l and m, the extension of k would have to pass through the pole of l and the pole of m. Hence, to construct k, we need only join these poles by a Euclidean line and take k to be the open chord of γ cut out by this line (Figure 7.17).[6]

There is a nice language that describes the behavior of pairs of lines in the Klein model. Let us call the points inside circle γ (which

---

[6] If l and m did have a common end Ω, the Euclidean line joining P(l) to P(m) would be tangent to γ at Ω. That is why Saccheri claimed that asymptotically parallel lines have "a common perpendicular at infinity," and this he found repugnant.

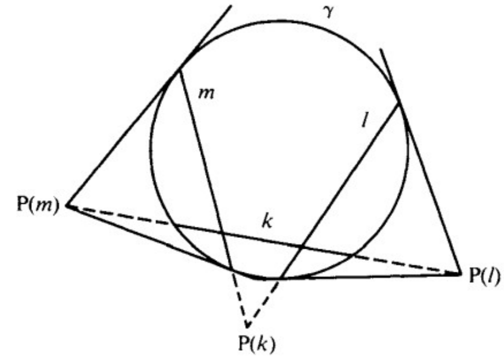

FIGURE 7.17

represent all the points in the hyperbolic plane) *ordinary points.* We already called the points on the circle γ *ideal points.* Let us call the points outside γ *ultra-ideal points.* Finally, for every diameter of γ, let us imagine another point "at infinity" such that all the Euclidean lines parallel in the Euclidean sense to this diameter meet in this point at infinity, just as railroad tracks appear to meet at the horizon. These points at infinity will also be called *ultra-ideal.* We can then say that two Klein lines "meet" at an ordinary point, an ideal point, or an ultra-ideal point, depending on whether they are intersecting, asymptotically parallel, or divergently parallel, respectively. The ultra-ideal point at which divergently parallel Klein lines l and m "meet" is the pole P(k) of their common perpendicular k (see Figure 7.17).

This language is suggestive of further theorems in hyperbolic geometry. For example, we know that two ordinary points determine a unique line, and we have seen that two ideal points also determine a unique line, the line of enclosure of Major Exercise 8, Chapter 6. We can ask the same question about two points that are ultra-ideal or about two points of different species. For example, an ordinary point and an ideal or ultra-ideal point always determine a unique line, but two ultra-ideal points may or may not (see Figure 7.18). Let us translate back from this language, say, in the case of an ordinary point O and an ultra-ideal point P(l) that is the pole of a Klein line l. What is the Klein line "joining" O to P(l)? It is the unique Klein line m through O that is perpendicular in the sense of the Klein model to the line l (see Figure 7.16). We leave the other cases for exercises.

If you did most of the exercises in hyperbolic geometry in Chapter 6, deriving results without having reliable diagrams to guide you, the

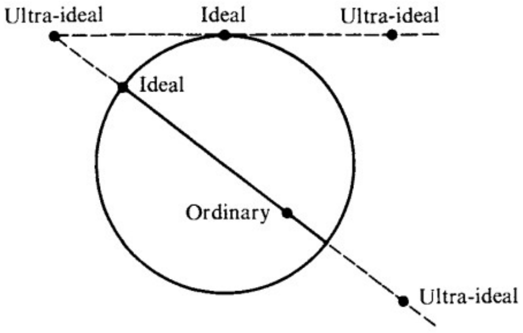

FIGURE 7.18

Klein and Poincaré models must come as a great relief. It is a useful exercise to take an absurd diagram like Figure 6.26 and draw those divergently parallel perpendicular bisectors of the triangle more accurately in one of the models. It is amazing that J. Bolyai and Lobachevsky were able to visualize hyperbolic geometry without such models, especially since they worked in three dimensions. They must have had non-Euclidean eyesight.

A MODEL OF THE HYPERBOLIC PLANE FROM PHYSICS

This model comes from the theory of special relativity. In Cartesian three-space $\mathbb{R}^3$, with coordinates denoted x, y and t (for *time*), distance will be measured by the Minkowski metric

$$ds^2 = dx^2 + dy^2 - dt^2.$$

Then with respect to the Minkowski metric, the surface of equation

$$x^2 + y^2 - t^2 = -1$$

is a "sphere" centered at the origin $O = (0, 0, 0)$ of imaginary radius $i = \sqrt{-1}$. (As was mentioned in Chapter 5, Lambert was the first to wonder if such a model existed.) In Euclidean terms, it is a two-sheeted *hyperboloid* (surface of revolution obtained by rotating the hyperbola $t^2 - x^2 = 1$ around the x axis). We choose the sheet Σ: $t \geq 1$ as our model. It looks like an infinite bowl (see Figure 7.19).

CHAPTER 8

PHILOSOPHICAL IMPLICATIONS

> I have had my solutions for a long time, but I do not yet know how I am to arrive at them.
>
> C. F. GAUSS

WHAT IS THE GEOMETRY OF PHYSICAL SPACE?

We have shown that if Euclidean geometry is consistent, so is hyperbolic geometry, since we can construct models for it within Euclidean geometry. Conversely, it can be proved that if hyperbolic geometry is consistent, so is Euclidean geometry, for the "horocycles" on the "horosphere" in hyperbolic space form a model of the lines on the Euclidean plane (see Kulczycki, 1961, §17). *Thus, the two geometries are equally consistent.*

You may grant now that, logically speaking, hyperbolic geometry deserves to be put on an equal footing with Euclidean geometry. But you may also feel that hyperbolic geometry is just an amusing intellectual pastime, whereas Euclidean geometry accurately represents the physical world we live in and is therefore far more important. Let's examine this idea a little more closely.

Certainly, engineering and architecture are evidence that Euclidean geometry is extremely useful for ordinary measurement of distances that are not too large. However, the representational accuracy of Euclidean geometry is less certain when we deal with larger distances. For example, let us interpret a "line" physically as the path traveled by a light ray. We could then consider three widely separated light sources forming a physical triangle. We would want to measure the angles of this physical triangle in order to verify whether the sum is 180° or not (such an experiment would presumably settle the question of whether space is Euclidean or hyperbolic).

F. W. Bessel, a friend of Gauss, performed such a measurement, using the angle of parallax of a distant star. The results were inconclusive. Why? Because any physical experiment involves experimental error. Our instruments are never completely accurate. Suppose the sum did turn out to be 180°. If the error in our measurement were at most 1/100 of a degree, we could conclude only that the sum was between 179.99° and 180.01°. We could never be sure that it actually was 180°.

Suppose, on the other hand, that measurement gave us a sum of 179°. Although we could conclude only that the sum was between 178.99° and 179.01°, we would be certain that the sum was less than 180°. In other words, the only conclusive result of such an experiment would be that space is hyperbolic![1] The inconclusiveness of Bessel's experiment shows only that if space is hyperbolic, the defects of terrestrial triangles are extremely small.

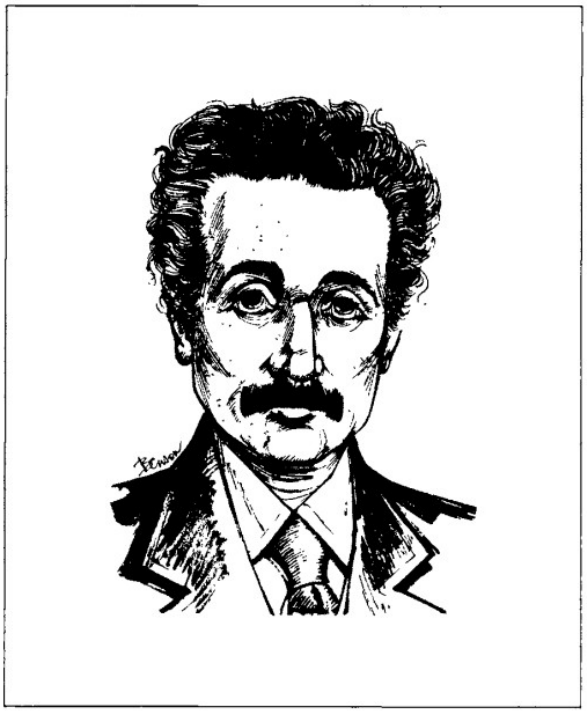
To repeat the point: Because of experimental error, a physical experiment can never prove conclusively that space is Euclidean — it can prove only that space is non-Euclidean.

The discussion can be made more subtle. We must question the nature of our instruments — aren't they designed on the basis of Euclidean assumptions? We must question our interpretation of "lines" — couldn't light rays travel on curved paths? We must question whether space, especially space of cosmic dimensions, cannot be described by geometries other than these two.

The latter is in fact our present scientific attitude. According to Einstein, space and time are inseparable and the geometry of space-time is affected by matter, so that light rays are indeed curved by the gravitational attraction of masses. Space is no longer conceived of as an empty Newtonian box whose contours are unaffected by the rocks put into it. The problem is much more complicated than Euclid or Loba-

---

[1] If the measurement gave us a sum of 181° with error at most .01°, we would conclude that space is elliptic.



Albert Einstein

chevsky ever imagined — neither of their geometries is adequate for our present conception of space. This does not diminish the historical importance of non-Euclidean geometry. Einstein said, "To this interpretation of geometry I attach great importance, for should I not have been acquainted with it, I never would have been able to develop the theory of relativity."[2]

Here is the famous response of Poincaré to the question of which geometry is true:

> If geometry were an experimental science, it would not be an exact science. It would be subjected to continual revision. . . . *The geometrical axioms are therefore neither synthetic a priori intuitions nor experimental*

---

[2] See George Gamow (1956), which tells how Einstein developed a geometry appropriate to general relativity from the ideas of Georg Friedrich Bernhard Riemann (1826–1866).

> *facts. They are conventions.* Our choice among all possible conventions is guided by experimental facts; but it remains free, and is only limited by the necessity of avoiding every contradiction, and thus it is that postulates may remain rigorously true even when the experimental laws which have determined their adoption are only approximate. In other words, *the axioms of geometry* (I do not speak of those of arithmetic) *are only definitions in disguise.* What then are we to think of the question: Is Euclidean Geometry true? It has no meaning. We might as well ask if the metric system is true and if the old weights and measures are false; if Cartesian coordinates are true and polar coordinates false. *One geometry cannot be more true than another: it can only be more convenient.* [italics added] [3]

You may think that Euclidean geometry is the most convenient — it is for ordinary engineering, but not for the theory of relativity. Moreover, R. K. Luneburg contends that visual space, the space mapped on our brains through our eyes, is most conveniently described by hyperbolic geometry.[4]

Philosophers are still arguing about Poincaré's philosophy of conventionalism. One school, which includes Newton, Helmholtz, Russell, and Whitehead, contends that space has an intrinsic metric or standard of measurement. The other school, which includes Riemann, Poincaré, Clifford, and Einstein, contends that a metric is stipulated by convention. The discussion can become very subtle (see Torretti, 1978, Chapter 4).

WHAT IS MATHEMATICS ABOUT?

The preceding discussion sheds new light on what geometry, and in general, mathematics, is about. Geometry is not about light rays, but the path of a light ray is one possible *physical interpretation* of the undefined geometric term "line." Bertrand Russell once said that "mathematics is the subject in which we do not know what we are

CHAPTER 10

FURTHER RESULTS IN HYPERBOLIC GEOMETRY

> The theorems of this geometry appear to be paradoxical and, to the uninitiated, absurd; but calm, steady reflection reveals that they contain nothing at all impossible.
>
> C. F. GAUSS

In this chapter we will penetrate more deeply into the "strange new universe" of hyperbolic geometry. To facilitate this adventure, we will sometimes glance quickly at certain unusual forms, not pausing for rigorous proofs of existence; at other times we will be more rigorous but allow ourselves to operate within the Klein or Poincaré models where our familiar Euclidean tools are available, instead of laboriously reasoning directly from the hyperbolic axioms. Hopefully, by the end of this excursion, the terrain will become sufficiently familiar to you that you will be comfortable enough to make further explorations with other guides.

AREA AND DEFECT

In 1799, in answer to a letter from Farkas Bolyai in which Bolyai claimed to have proved Euclid's fifth postulate, Gauss wrote:

> . . . the way in which I have proceeded does not lead to the desired goal, the goal that you declare you have reached, but instead to a doubt of the validity of [Euclidean] geometry. I have certainly achieved

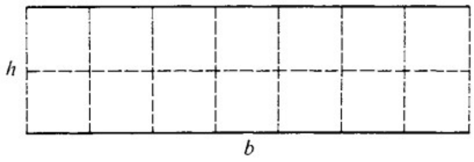

FIGURE 10.1 Area = bh.

> results which most people would look upon as proof, but which in my eyes prove almost nothing; if, for example, one can prove that there exists a right triangle whose area is greater than any given number, then I am able to establish the entire system of [Euclidean] geometry with complete rigor. Most people would certainly set forth this theorem as an axiom; I do not do so, though certainly it may be possible that, no matter how far apart one chooses the vertices of a triangle, the triangle's area still stays within a finite bound. I am in possession of several theorems of this sort, but none of them satisfy me.[1]

One of the most surprising facts in hyperbolic geometry is that there is an upper limit to the possible area a triangle can have, even though there is *not* an upper limit to the lengths of the sides of the triangle.

To see how this can be, we have to review the way in which area is calculated in Euclidean geometry. The simplest figure is a rectangle, whose area we calculate as the length of the base times the length of the side (Figure 10.1). This formula is arrived at by noticing that exactly bh unit squares fill up the interior of the rectangle, where a unit square is a square whose side has length one. Keep in mind that the unit of length is arbitrary, so that if we measure area in square inches, we get a different number than if we measure in square feet (but the latter number is always proportional to the former, the proportionality factor being $144 = 12^2$).

From the area of a rectangle we can calculate the area of a right triangle. A diagonal of a rectangle divides it into two congruent right triangles, and since we want congruent triangles to have the same area, the area of the right triangle must be half the area of the rectangle. (See Figure 10.2.)

We can decompose the interior of an arbitrary triangle into the union of the interiors of two right triangles by dropping an appropriate

---

[1] R. Bonola (1955).

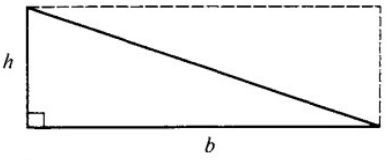

FIGURE 10.2 Area $= \frac{1}{2}bh$.

altitude. Since we want the area of the whole to be the sum of the area of its parts, we find the area of the triangle to be $\frac{1}{2}b_1h + \frac{1}{2}b_2h$, and since $b = b_1 + b_2$, we again get half the base times the height for the area of a general triangle (Figure 10.3).

You can see that by taking b and h to be sufficiently large, the area $\frac{1}{2}bh$ can be made as large as you like.

So why doesn't this work equally well in hyperbolic geometry? Because the whole system of measuring area is based on square units, and as we have seen (Lemma 6.1) rectangles (in particular, squares) do not exist in hyperbolic geometry.

What then does "area" mean in hyperbolic geometry? We can certainly say intuitively that it is a way of assigning to every triangle a certain positive number called its *area,* and we want this area function to have the following properties:

1. *Invariance under congruence.* Congruent triangles have the same area.
2. *Additivity.* If a triangle T is split into two triangles T_1 and T_2 by a segment joining a vertex to a point of the opposite side, then the area of T is the sum of the areas of T_1 and T_2 (Figure 10.4).

Having defined area, we then ask how it is calculated. It can be proved rigorously that in hyperbolic geometry the area of a triangle cannot be calculated as half the base times the height (see Moise, 1990, p. 411). So how do you calculate it? Here we find one of the

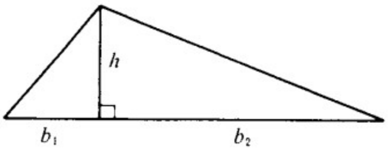

FIGURE 10.3 Area $= \frac{1}{2}bh$ where $b = b_1 + b_2$.

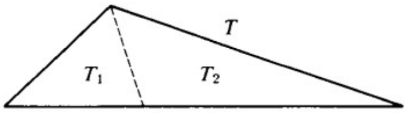

FIGURE 10.4 Area $T =$ area $T_1 +$ area T_2.

most beautiful aspects of mathematics, a direct relationship between two concepts that at first seem totally unrelated. You may have recognized this relationship in reading area properties 1 and 2, for in Theorem 4.7 and Exercise 1, Chapter 4, we proved that the *defect* also has these properties. Recall that in hyperbolic geometry the angle sum of any triangle is always less than 180° (Theorem 6.1), so that if we define the defect to be 180° minus the angle sum, we get a positive number. When a mathematician sees two functions with the same properties, he suspects they are related. Gauss discovered this relationship as early as 1794 (he was only 17 years old), and called it the first theorem in the subject.[2]

THEOREM 10.1. In hyperbolic geometry there is a positive constant k such that for any $\triangle ABC$

$$\text{area}(\triangle ABC) = \frac{\pi}{180} k^2 \times \text{defect}(\triangle ABC).$$

For the proof, which is not difficult although it is somewhat lengthy, see Moise (1990, p. 413). The theorem says that the area of any triangle is proportional to its defect, with proportionality constant $(\pi/180)k^2$. This constant depends on the unit of measurement, i.e., on whichever triangle is taken to have area equal to 1.

We can now see why there is an upper limit to the area of all triangles. Namely, the defect measures how much the angle sum is less than 180. Since the angle sum can never get below 0, the defect can never get above 180. Thus, we have the following corollary.

---

[2] This theorem seems to imply that Euclidean and hyperbolic area theories have little in common. Yet J. Bolyai discovered a wonderful theorem on area that is valid in *both* geometries. Define the area of a polygon to be the sum of the areas of the triangles used to triangulate the polygon. (It is not difficult to show that this definition does not depend on the choice of triangulation.) Bolyai's theorem states that two polygons S and S' have the same area if and only if for some n, polygon S (respectively, S') has a triangulation $\{T_1, \ldots, T_n\}$ (respectively, $\{T'_1, \ldots, T'_n\}$) such that $T_j \cong T'_j$ for all $j = 1, \ldots, n$. (For a proof, see E. E. Moise (1990, pp. 394–410). To appreciate the depth of this theorem, try to prove it for two rectangles in the Euclidean plane.)

COROLLARY. In hyperbolic geometry the area of any triangle is at most πk^2.

Of course, there is no finite triangle whose area equals the maximal value πk^2, although we can approach this area as closely as we wish (and achieve it with an infinite trebly asymptotic triangle). However, J. Bolyai showed how to construct a *circle* of area πk^2 and a regular 4-sided polygon with a 45° angle that also has this area (see Exercise 29 or Bonola, 1955, pp. 106–110).

If we interpret hyperbolic geometry in our physical world, it is clear that since defects of terrestrial triangles are immeasurably small, while their areas are measurable, the proportionality constant k^2 must be extremely large. According to Kulczycki (1961, pp. 153–155) the measurements of the parallaxes of fixed stars "elicit that the constant k is not less than about six hundred trillion miles." Thus, $k^2 > 36 \times 10^{28}$. These measurements are based on the fact that the right triangle whose one side is half the major axis of the earth's orbit around the sun and whose opposite vertex is at a fixed star has defect less than the parallax of the star (Figure 10.5). Of course, since Einstein, we do not use hyperbolic geometry to model the geometry of the universe.

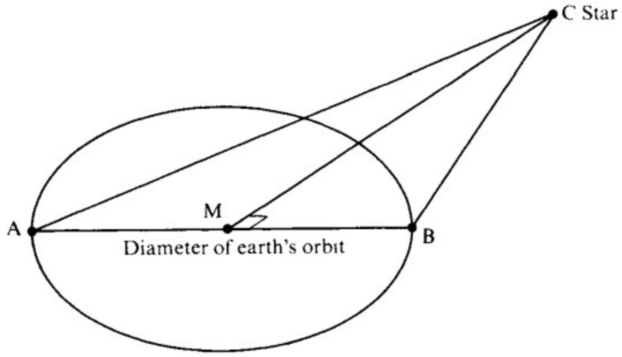

FIGURE 10.5 Defect $(\triangle ACM)^\circ = 90^\circ - (\sphericalangle CAM)^\circ - (\sphericalangle ACM)^\circ < 90^\circ - (\sphericalangle CAM)^\circ =$ parallax.

THE ANGLE OF PARALLELISM

Recall that given any line l and any point P not on l, there exist limiting parallel rays $\overrightarrow{PX}$ and $\overrightarrow{PY}$ to l that are situated symmetrically about the perpendicular PQ from P to l (Figure 10.6; see Chapter 6). We proved that $\sphericalangle XPQ \cong \sphericalangle YPQ$ (Theorem 6.6), so either of these angles can be called the *angle of parallelism* for P with respect to l.

It is not difficult to show that the number α of radians in the angle of parallelism depends only on the distance d from P to Q, not on the particular line l or the particular point P (see Major Exercise 5, Chapter 6). In the notation used after the proof of Theorem 6.6, $\alpha = (\pi/180)\Pi(PQ)^\circ$.

The following formula relating α and d was discovered by J. Bolyai and Lobachevsky.

THEOREM 10.2. Formula of Bolyai-Lobachevsky:

$$\tan\frac{\alpha}{2} = e^{-d/k}$$

where k is the constant whose square occurs in the proportionality factor of area to defect in Theorem 10.1.

This is certainly one of the most remarkable formulas in all of mathematics, and it is astonishing how few mathematicians know it. In this formula the number e is the base for the natural logarithms (e is approximately 2.718 . . .), and $\tan \alpha/2$ is the trigonometric tangent of half of α. Proofs of this formula will be found in Kulczycki (1961, §20) and in Borsuk and Szmielew (1960, Chapter 6, §26). We have checked this formula for the Poincaré disk model (where $k = 1$) —see Theorem 7.2, p. 256.

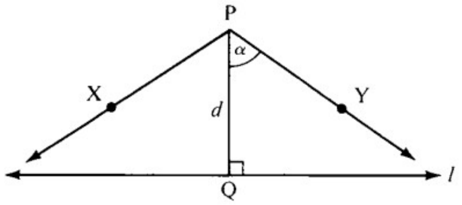

FIGURE 10.6

CYCLES

The various proofs of the Bolyai-Lobachevsky formula (Theorem 10.2) all make use of a curve that is peculiar to hyperbolic geometry, called either a *limiting curve* or a *horocycle* in the literature. It is obtained as follows (see also Exercises 41–44, Chapter 9).

Start with a line *l*, point Q on *l*, and erect perpendicular $\overleftrightarrow{PQ}$ to *l* through Q. Then consider the circle δ with center P and radius PQ, which is tangent to *l* at Q (see Figure 10.7). Now let P recede from *l* along the perpendicular. The circle δ will increase in size, remaining tangent to *l*, and will approach a limiting position as P recedes arbitrarily far from Q. In Euclidean geometry the limiting position of δ would just be the line *l*, but in hyperbolic geometry the limiting position of δ is a new curve *h* called a *limiting curve* or *horocycle.*

We can visualize this in the Poincaré model as follows. Let *l* be a diameter of the Euclidean circle γ whose interior represents the hyperbolic plane, and let Q be the center of γ. It can be proved that the hyperbolic circle with hyperbolic center P is represented by a Euclidean circle whose Euclidean center R lies between P and Q (Exercise P-5, Chapter 7); see Figure 10.8.

As P recedes from Q toward the ideal point represented by S, R is pulled up to the Euclidean midpoint of SQ, so that the horocycle *h* is a Euclidean circle tangent to γ at S and tangent to *l* at Q. It can be shown in general that all horocycles are represented in the Poincaré model by Euclidean circles inside γ and tangent to γ. Moreover, all the Poincaré lines passing through the ideal point S are orthogonal to *h*; a hyperbolic ray from a point of *h* out to the ideal point S is called a *diameter* of *h* (see Chapter 9, Exercises 41, 44, and 46).

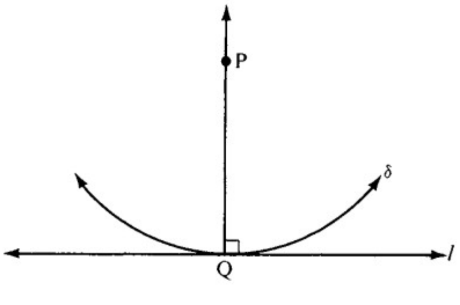

FIGURE 10.7

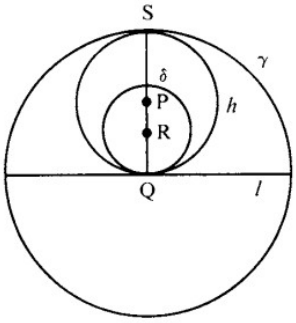

FIGURE 10.8

In the Poincaré model two horocycles tangent to γ at S are said to be *concentric* (see Figure 10.9). It is by studying the ratio of corresponding arcs on concentric horocycles that the Bolyai-Lobachevsky formula can be derived (see Kulczycki, 1961, §18).

There is an analogous construction in hyperbolic space called the *horosphere.* Instead of taking the limit of circles to get the horocycle, one takes the limit of spheres to get the horosphere or *limiting surface.*

Another strange curve in hyperbolic geometry that has no Euclidean counterpart is the *equidistant curve* (Figure 10.10). Start with a line l and a point P not on l. Consider the locus of all points on the same side of l as P and at the same perpendicular distance from l as P. In Euclidean geometry this locus would just be the unique line through P parallel to l, but in hyperbolic geometry it is not a line, it is the *hypercycle,* or *equidistant curve,* through P.

In the Poincaré model let A and B be the ideal endpoints of l. It turns out that the equidistant curve to l through P is represented by

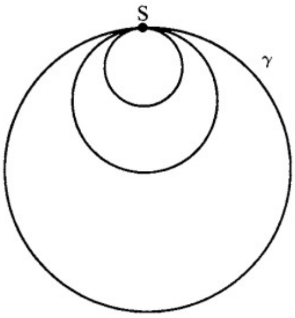

FIGURE 10.9 Concentric horocycles.

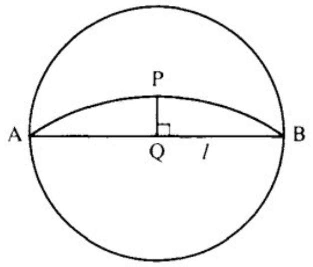

FIGURE 10.10 Equidistant curve.

the arc of the Euclidean circle passing through A, B, and P (Chapter 9, Exercises 40, 45, and 47). This curve is orthogonal to all Poincaré lines perpendicular to the line *l*.

In the Euclidean plane three points either lie on a uniquely determined line or on a uniquely determined circle. Not so in the hyperbolic plane—look at the Poincaré model. A Euclidean circle represents:

1. A *hyperbolic circle* if it is entirely inside γ;
2. A *horocycle* if it is inside γ except for one point where it is tangent to γ;
3. An *equidistant curve* if it cuts γ nonorthogonally in two points;
4. A *hyperbolic line* if it cuts γ orthogonally.

It follows that in the hyperbolic plane three noncollinear points lie either on a circle, a horocycle, or a hypercycle accordingly as the perpendicular bisectors of the triangle are "concurrent" in an ordinary, ideal, or ultra-ideal point—see the last section of this chapter.

THE PSEUDOSPHERE

One of the difficulties with the Poincaré model is that, although it faithfully represents angles of the hyperbolic plane (i.e., it is a *conformal model*), it distorts distances. So it is natural to ask whether another model exists that also represents hyperbolic lengths faithfully by Euclidean lengths. If there is such a model, it would be called *isometric*. An equally natural idea is to seek as a model some surface in Euclidean three-dimensional space. The lines of the hyperbolic plane would

5- 6 <26673

(8) The representation by Weierstrass coordinates helps make sense of Lambert's description of the hyperbolic plane as a "sphere of imaginary radius *i*."

(9) The curvature of the hyperbolic plane is $1/k^2$, where k^2 times the defect in radians equals the area of a triangle.

(10) The analogue of the Pythagorean theorem is the formula $\cosh c = \cosh a \cosh b$ (for a right triangle with right angle at C, standard notation, $k = 1$).

EXERCISES

1. Verify all the identities for hyperbolic functions listed in the table on p. 401.
2. Verify formulas (5), (6), (7) in which Π provides a link between hyperbolic and circular functions. Graph the function $\Pi(x)$.
3. The proof of Theorem 10.3 required a complicated argument using the Poincaré model. Give a different proof using the Klein model. (Hint: According to the note at the end of Chapter 7, you can assume A = O, the center of the absolute. Show that $\cos A = \overline{AC}/\overline{AB}$ and $\sin A = \overline{BC}/\overline{AB}$ (Euclidean lengths), $\overline{AB} = \tanh c$ (where $c = d'(AB)$ is the Klein length), $\overline{AC} = \tanh b$, and $\overline{BC} = (1 - \overline{AC}^2)^{1/2} \tanh a = \tanh a/\cosh b$ (use Theorem 7.4). Conclude by deducing the formula $\cosh c = \cosh a \cosh b$ from the Pythagorean theorem. See Figure 10.29.)
4. Prove Theorem 10.4.

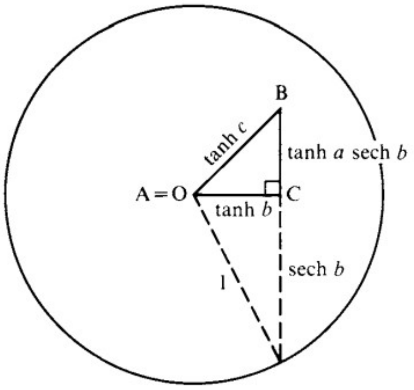

FIGURE 10.29

5. Verify step 2 in the proof of Theorem 10.6.
6. Verify formulas (18) through (21) for complementary lengths. Graph the function
$$f(x) = x^* = \ln \frac{e^x + 1}{e^x - 1}.$$
7. Prove the assertions about Weierstrass coordinates in Theorem 10.10. (Hint: Derive the equation of a line in Weierstrass coordinates from the equation of a line in Beltrami coordinates.)
8. Verify formulas (28) and (29) in the proof of Theorem 10.10 and use them to reconcile with the distance formula in Exercise K-14, Chapter 7.
9. Generalize Lemmas 10.1 and 10.2 by showing that if (x_1, y_1) and (x_2, y_2) are distinct points in the Klein model, then the midpoint and perpendicular bisector of the segment they determine are given respectively by
$$\left(\frac{x_1s_2 + x_2s_1}{s_1 + s_2}, \frac{y_1s_2 + y_2s_1}{s_1 + s_2}\right)$$
$$(x_1s_2 - x_2s_1)x + (y_1s_2 - y_2s_1)y + (s_1 - s_2) = 0$$
where $s_i = \sqrt{1 - x_i^2 - y_i^2}$, $i = 1, 2$. (Hint: Use Lemma 10.2 to find the point Q in the Cartesian plane where the perpendicular bisectors of OP_1 and OP_2 meet. Then joining Q to the pole of $\overleftrightarrow{P_1P_2}$ gives the perpendicular bisector of P_1P_2, and intersecting it with P_1P_2 gives the midpoint.)
10. Prove the corollary to Theorem 10.11.
11. In a right triangle with right angle at C, prove that the circumscribed cycle is a
$$\left.\begin{matrix}\text{Circle}\\ \text{Horocycle}\\ \text{Equidistant curve}\end{matrix}\right\} \Leftrightarrow \frac{a}{2} \left\{\begin{matrix} < \\ = \\ > \end{matrix}\right\} \left(\frac{b}{2}\right)^*.$$
(Hint: Apply the second criterion of Theorem 10.11 with $\sphericalangle$C the largest angle, using the fact that Π is a decreasing function. Or else argue directly from the definition of complementary lengths.)
12. Verify A. P. Kotelnikov's rule for remembering the relations among the parts of a right triangle with the right angle at C, standard notation (x^* denoting the complementary length to x): in Figure 10.30, *the sine of each angle is equal to the product of the tangents of the two adjacent angles and is equal to the product of the cosines of the two opposite angles.* For example,
$$\sin A = \tan \Pi(a^*) \tan \Pi(c) = \cos \Pi(b^*) \cos B.$$
(This rule is the hyperbolic analogue of the rule John Napier published in 1614 for the trigonometry of a right triangle on a unit sphere in

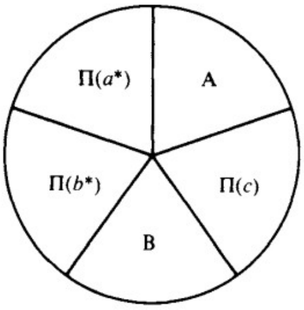

FIGURE 10.30

Euclidean space. For Napier's rule, use a, b, A′, c', B′ in cyclic order, where A′ denotes the complementary angle to ∢A and $c' = \pi/2 - c$. J. Bolyai and Lobachevsky discovered that spherical trigonometry in hyperbolic space is the same as in Euclidean space.)

13. In Euclidean geometry, every circle can be inscribed in a triangle (the tangents at three appropriate points on the circle meet to form a triangle). Show that in hyperbolic geometry (with $k = 1$), an inscribed circle of a triangle must have diameter less than ln 3. (Hint: In Figure 10.32, show that $(\sphericalangle \text{AIB}')^r + (\sphericalangle \text{BIC}')^r + (\sphericalangle \text{CIA}')^r = \pi$, and that each of these three angles is less than $\Pi(r)$; then apply the Bolyai-Lobachevsky formula to find x such that $\Pi(x) = \pi/3$.)
14. Show that (with $k = 1$) a trebly asymptotic triangle has an inscribed circle of diameter ln 3 (see Exercise K-13, Chapter 7). Show that the area of this circle is
$$2\pi\left(\frac{2}{\sqrt{3}} - 1\right)$$
and its circumference is $2\pi/\sqrt{3}$ (use Theorems 10.5 and 10.7).
15. Show that for any three positive numbers α, β, γ such that $\pi < \alpha + \beta + \gamma$, there exists a triangle having these numbers as the radian measures of its angles. (Hint: Use Theorem 10.4.)
16. In a singly asymptotic triangle ABΩ, if $c = \overline{\text{AB}}$, then
$$\cosh c = \frac{\cos \text{A} \cos \text{B} + 1}{\sin \text{A} \sin \text{B}}.$$
(Hint: Let C approach Ω in formula (15), Theorem 10.4. For a proof without using continuity, note that when ∢A and ∢B are acute,
$$c = \Pi^{-1}(\alpha) + \Pi^{-1}(\beta),$$
where $\alpha = (\sphericalangle\text{A})^r$, $\beta = (\sphericalangle\text{B})^r$—see Figure 10.31.) Show that the gen-

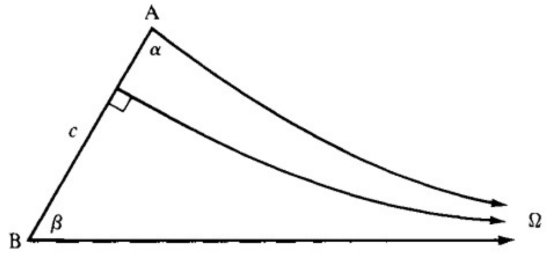

FIGURE 10.31

eralization of the Bolyai-Lobachevsky formula to the case when $\beta < \pi/2$ is

$$\tan\frac{\alpha}{2} = e^{-c}\cot\frac{\beta}{2}.$$

17. Write down equations which show how the side and the angle of an equilateral triangle determine each other.
18. (a) In a right triangle with standard notation and right angle at C, show that $\tan A = \tanh a/\sinh b$.
    (b) Deduce that in an isosceles triangle with base b and side a, summit at B, and one base angle at A,

$$\tanh a \cos\frac{B}{2} = \tan A \sinh\frac{b}{2}$$

$$\sin A \cosh\frac{b}{2} = \cos\frac{B}{2}.$$

    (Hint: Drop the altitude to the base.)
19. In a right triangle ΔABC with right angle at C (and standard notation), show that

$$\sin K = \frac{\sinh a \sinh b}{1 + \cosh a \cosh b},$$

    where K = the area = the defect of ΔABC. (Hint: Use Theorem 10.3 and trigonometric identities.)
20. Given ΔABC, if h is the length of the altitude from vertex B, show that (in standard notation) the product $\sinh b \sinh h$ is independent of the choice of which vertex is labeled B; this is the hyperbolic analogue of the Euclidean theorem that bh is constant. (Hint: Show that $\sinh b \sinh h = S \sinh a \sinh b \sinh c$, where S is the constant ratio occurring in the law of sines.) The next exercises will shed light on the

geometric significance of the constant $\frac{1}{2}\sinh b \sinh h$, which we will denote by H (for Heron); by the hint, $2H = \sin C \sinh a \sinh b = \sin B \sinh c \sinh a = \sin A \sinh b \sinh c$.

In Exercises 21–28, s will denote the *semiperimeter* $\frac{1}{2}(a+b+c)$ of $\triangle ABC$.

21. Show that (in standard notation)

$$\sin\frac{A}{2} = \sqrt{\frac{\sinh(s-b)\sinh(s-c)}{\sinh b \sinh c}}$$
$$\cos\frac{A}{2} = \sqrt{\frac{\sinh s \sinh(s-a)}{\sinh b \sinh c}}.$$

(Hint: Square both sides; use identities and Theorem 10.4.)

22. Show that $H = \sqrt{\sinh s \sinh(s-a)\sinh(s-b)\sinh(s-c)}$. (Hint: Use the identity $\sin A = 2\sin(A/2)\cos(A/2)$.)
23. "Infinitesimally," the Heron is equal to $\sqrt{s(s-a)(s-b)(s-c)}$. Show that in Euclidean geometry, this quantity is equal to the area of $\triangle ABC$. (Hint: See Coxeter, 1969, p. 12.)
24. Suppose the inscribed circle of $\triangle ABC$ has radius r and touches BC at A′, CA at B′, and AB at C′. Show that in neutral geometry, $\overline{AB'} = s - a = \overline{AC'}$, $\overline{BC'} = s - b = \overline{BA'}$, $\overline{CA'} = s - c = \overline{CB'}$ (see Figure 10.32). (Hint: Review the construction of the inscribed circle in Exercise 16, Chapter 6.)
25. Deduce from Exercise 24 that in hyperbolic geometry

$$\tanh r \sinh s = H$$

whereas in Euclidean geometry $rs =$ the area of $\triangle ABC$. (Hint: In hyperbolic geometry, use Exercises 18, 21, 22, and 24 to compute $\tan(A/2)\sinh(s-a)$; in Euclidean geometry, add up the areas of triangles IAB, IBC, and ICA in Figure 10.32.)

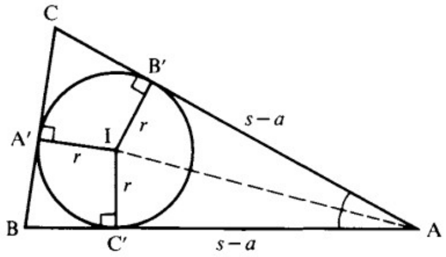

FIGURE 10.32

26. Prove Gauss' equations:

$$\begin{aligned}\cosh \tfrac{1}{2} c \sin \tfrac{1}{2} (\mathrm{A}+\mathrm{B}) &= \cosh \tfrac{1}{2} (a-b) \cos \tfrac{1}{2} \mathrm{C}\\ \cosh \tfrac{1}{2} c \cos \tfrac{1}{2} (\mathrm{A}+\mathrm{B}) &= \cosh \tfrac{1}{2} (a+b) \sin \tfrac{1}{2} \mathrm{C}\\ \sinh \tfrac{1}{2} c \sin \tfrac{1}{2} (\mathrm{A}-\mathrm{B}) &= \sinh \tfrac{1}{2} (a-b) \cos \tfrac{1}{2} \mathrm{C}\\ \sinh \tfrac{1}{2} c \cos \tfrac{1}{2} (\mathrm{A}-\mathrm{B}) &= \sinh \tfrac{1}{2} (a+b) \sin \tfrac{1}{2} \mathrm{C}.\end{aligned}$$

(Hint: Use identities such as

$$\sinh x + \sinh y = 2 \sinh \tfrac{1}{2} (x+y) \cosh \tfrac{1}{2} (x-y)$$

and analogous identities for the circular functions, then apply the half-angle formulas of Exercise 21.)

27. Show that a hyperbolic analogue of Heron's Euclidean area formula in Exercise 23 is the formula

$$\sin \frac{K}{2} = \frac{H}{2 \cosh \frac{a}{2} \cosh \frac{b}{2} \cosh \frac{c}{2}},$$

where K = area = defect of $\triangle$ABC. (Hint: Use Gauss' equations, the identity $\sin K/2 = \cos \tfrac{1}{2}(\mathrm{A}+\mathrm{B}+\mathrm{C})$, other trigonometric identities, and the formula $H = \tfrac{1}{2} \sin \mathrm{C} \sinh a \sinh b$.)

28. If $\triangle$ABC has a circumscribed circle of radius R, show that

$$\tanh R = \frac{2 \sinh \frac{a}{2} \sinh \frac{b}{2} \sinh \frac{c}{2}}{H},$$

which by Exercise 27 is equivalent to formula (30) of Theorem 10.12. (Hint: In Figure 10.33 $\sin \mathrm{A} = \sin (\beta' + \gamma')$, $H = \tfrac{1}{2} \sin \mathrm{A} \sinh b \sinh c$;

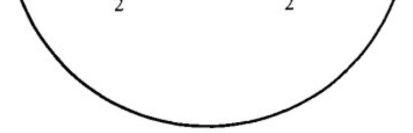

FIGURE 10.33

use Theorem 10.3 to determine $\cos \gamma'$ and $\cos \beta'$, and use Exercise 18 to determine $\sin \gamma'$ and $\sin \beta'$, obtaining with the help of identities the formula

$$H \tanh R = \left[\cos \frac{\gamma}{2} \sinh \frac{b}{2} + \cos \frac{\beta}{2} \sinh \frac{c}{2}\right] 2 \sinh \frac{b}{2} \sinh \frac{c}{2}.$$

Show finally that the term in brackets equals $\sinh a/2$ by using Theorem 10.3 to derive expressions for $\sinh a/2$, $\sinh b/2$, and $\sinh c/2$ and plugging in $\sin (\gamma + \beta)/2 = \sin \alpha/2$.)

29. Let $\Omega\Sigma\Lambda$ be a trebly asymptotic triangle and $\triangle$ABC its *pedal triangle* formed by the feet of the perpendiculars from each ideal vertex to the opposite side. Since all trebly asymptotic triangles are congruent to one another by Proposition 9.16(c), $\triangle$ABC is equilateral. Show that in the Poincaré upper half-plane model, the radian measure θ of an angle of $\triangle$ABC is given by $\tan \frac{1}{2}\theta = \frac{1}{2}$ or $\tan \theta = \frac{4}{3}$, $\sin \theta = \frac{4}{5}$, $\cos \theta = \frac{3}{5}$, and the length c of a side is given by $\cosh c = \frac{3}{2}$. Deduce that *a circle whose radius is a side of* $\triangle$ABC *has area equal to* π. Show further that the Heron H, the circumradius R, and the inradius r of $\triangle$ABC are given by

$$\begin{aligned} H &= \tfrac{1}{2} \\ \tanh R &= \tfrac{1}{2} \\ \tanh r &= \tfrac{1}{4}. \end{aligned}$$

(Hint: There are many ways to obtain these results using the previous exercises and the models. In the Poincaré upper half-plane model, taking $\Omega = -1$, $\Sigma = \infty$, $\Lambda = 1$ gives $A = i$, $B = 1 + 2i$, $C = -1 + 2i$. Show that $\overleftrightarrow{BC}$ is the upper semicircle of $x^2 + y^2 = 5$, $\overleftrightarrow{AB}$ the upper semicircle of $(x - 2)^2 + y^2 = 5$, and that the tangents to these circles at B have slopes $-\frac{1}{2}$, $\frac{1}{2}$, respectively.

This and the double angle formulas yield the assertions about θ. Exercises 18(a), 20, 25, and 28 can then be applied. Or use the Klein model, choosing $\Omega\Sigma\Lambda$ so that the origin is the incenter and circumcenter of $\triangle$ABC.)

Exercises 30–33 develop some more trigonometric formulas that William Thurston uses in his application of hyperbolic geometry to topology; see Casson and Bleiler (1988).

30. Given a quadrilateral with two adjacent right angles, labeled as in Figure 10.34. Prove that

$$\cosh d = \cosh a \cosh b \cosh c - \sinh a \sinh c.$$

(Hint: Imitate the proof of Theorem 10.8.)

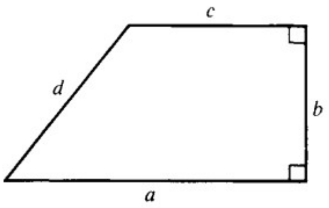

FIGURE 10.34

31. Given a pentagon with at least four right angles, labeled as in Figure 10.35. Prove that

$$\sinh e \cosh a = \sinh c \cosh b.$$

(Hint: Drop altitude h from the fifth vertex to the opposite side and apply the corollary to Theorem 10.8 to the two Lambert quadrilaterals obtained.)

32. Given a pentagon with five right angles (in Exercise K-5, Chapter 7, you showed that such pentagons exist), labeled as in Figure 10.36. Prove that

$$\cosh d = \sinh a \sinh b = \coth c \coth e.$$

(Hint: Here is one method; perhaps you can find one simpler: first apply Exercise 31 five times to all the combinations of four consecutive sides; then by considering the broken lines in Figure 10.36 and Exercise 30 and Theorem 10.3, deduce the equations

$$\cosh a \cosh b \left(\frac{\cosh c}{\cosh e}\right) - \sinh a \left(\frac{\sinh c}{\cosh e}\right)$$
$$= \cosh d = \cosh a \cosh b \left(\frac{\cosh e}{\cosh c}\right) - \sinh b \left(\frac{\sinh e}{\cosh c}\right).$$

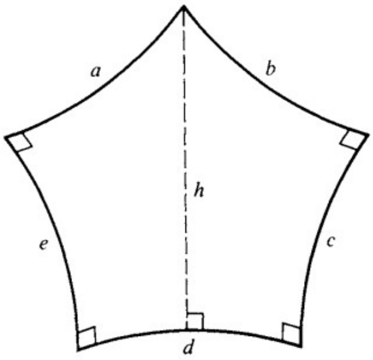

FIGURE 10.35

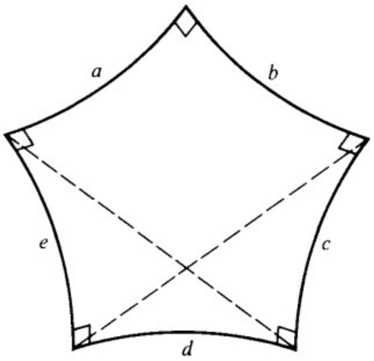

FIGURE 10.36

Substitute for the terms in parentheses from four of the earlier equations and do some algebra using the identity $\cosh^2 x = 1 + \sinh^2 x$ to get the result.)

33. In an all right-angled hexagon (again review Exercise K-5, Chapter 7) labeled as in Figure 10.37, prove the following remarkable analogues of the laws of sines and cosines given in Theorem 10.4 for a triangle:

$$\frac{\sinh a}{\sinh \alpha} = \frac{\sinh b}{\sinh \beta} = \frac{\sinh c}{\sinh \gamma}$$

$$\cosh a = \frac{\cosh \beta \cosh \gamma + \cosh \alpha}{\sinh \beta \sinh \gamma}.$$

(Hint: First show that the common perpendicular segment of length h falls inside the hexagon as shown; then apply Exercise 32 to the two all right-angled pentagons to get two expressions for $\cosh h$ and obtain the "law of sines"; for the "law of cosines," apply Exercise 32 to get expressions for $\cosh a$, $\cosh \beta$, $\cosh \alpha$, and $\cosh h$, use Exercise 31 to eliminate $\sinh c_1$, and use the identity for $\sinh \gamma_2 = \sinh(\gamma - \gamma_1)$.)

5- 66 26N 3 ( )) #   +

Clifford-parallel if they are equidistant from each other; the lines are joined to each other by a continuous family of common perpendicular segments of the same length. Such lines cannot lie in a plane (in an elliptic plane two lines must intersect), so they are skew lines. Moreover, in general, in elliptic space for any point P not on a line *l* there exist exactly two lines through P that are Clifford-parallel to *l*, called the *right and left Clifford parallels* to *l* through P. We say "in general" because there is a special line l^*, called the *absolute polar* of *l*: if P lies on l^*, there is only one Clifford parallel to *l* through P, which is l^*. (Naturally, this is difficult to visualize! See Coxeter, 1968, Chapter 7.)

Elliptic space is finite but unbounded—finite because all lines have finite length and look like circles, and unbounded because there is no boundary, just as on the surface of a sphere there is no boundary. In a universe having this geometry, with light rays traveling along elliptic lines, you could conceivably look through a very powerful telescope and see the back of your own head! (Although you might have to wait a few billion years for the light to travel all the way around.)

RIEMANNIAN GEOMETRY

It is impossible to rigorously explain the ideas of Riemannian geometry without using the language of the differential and integral calculus, so in this appendix we can only attempt to understand very roughly the intuitive idea. The basic notion we shall attempt to grasp is *curvature.*

The two simplest smooth one-dimensional figures in the Euclidean plane are a line and a circle. We think of a line as being "straight" i.e., not curved, so that if we were to assign any numerical curvature k to a line, we would assign the value $k = 0$. A circle γ, on the other hand, is certainly "curved," and how much it is curved depends on its radius r. The larger the radius of γ, the more γ approaches a line, i.e., the less it curves; it is therefore natural to define the curvature k of a circle of radius r by $k = 1/r$ (the curvature is inversely proportional to the radius); see Figure A.7.

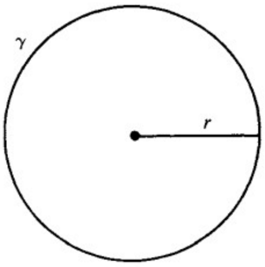

FIGURE A.7 Curvature $k = 1/r$.

Consider next an arbitrary smooth curve γ in the Euclidean plane. By "smooth curve" we mean one that has a continuously turning tangent line at each point. The tangent to a point on a circle is the perpendicular to the radius at that point. We can define the tangent to a point P on general curve γ as follows. P and another point Q on γ determine a line l. We fix point P and let Q approach P. The limiting position achieved by line l as Q approaches P is by definition the *tangent line t* to γ at P (see Figure A.8).

Besides the fixed point P, we can also consider two other points P_1 and P_2 on γ. These three points determine a circle δ. Fix P and let P_1 and P_2 both approach P along γ. The limiting position of circle δ as P_1 and P_2 approach P is the circle that "best fits" the curve γ at P, and is called the *osculating circle* to γ at P (from the Latin *osculari,* "to kiss"); see Figure A.9. It is reasonable to define the *curvature* of γ at P as the curvature of its osculating circle at P, i.e., the reciprocal $k = 1/r$ of the radius r of the osculating circle (r is also called the *radius of curvature* of γ at P).

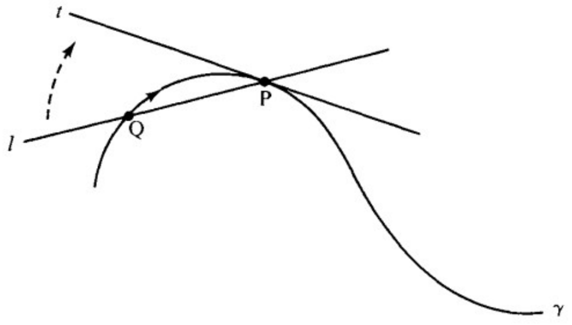

FIGURE A.8

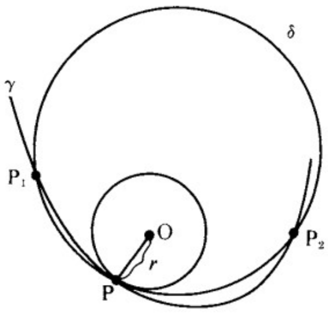

FIGURE A.9

It is clear from Figure A.10 that the osculating circle will vary in size as we move along the curve γ, so that the curvature k varies from point to point along γ. Notice also that the tangent to γ at a point P is also the tangent to the osculating circle at P.

Notice also in Figure A.10 that the osculating circle may be on different sides of the curve γ. It is convenient to *redefine curvature* so that it is positive on one side of γ and negative on the other. Once this is done, it becomes clear that in Figure A.10 there must be a point I between A and B on γ at which the curvature is zero, since we assume γ is smooth enough for the curvature to vary continuously. This point I is called a *point of inflection,* and at such a point the osculating "circle" degenerates into a line, the tangent line at I (see Figure A.11).

What we have said about plane curves applies equally well to curves in Euclidean space, with the following modifications. The osculating circle lies in a unique plane through P called the *osculating plane* Π of γ at P (except in the degenerate case of a point P at which γ has curvature zero). Since Π varies with P if γ is not a plane curve, we no longer have a smooth way to assign positive and negative values to the

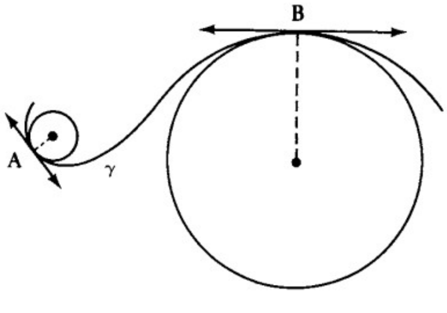

FIGURE A.10

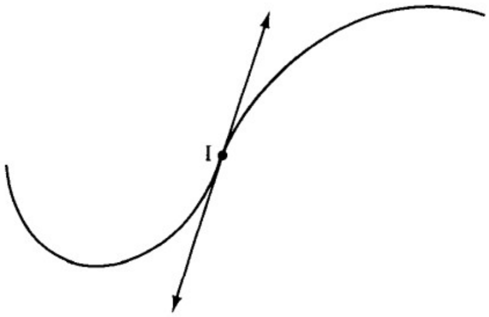

FIGURE A.11 Point of inflection $k = 0$.

curvature. We assign a *curvature vector* **k** lying in the osculating plane, emanating from P and perpendicular to the tangent line to γ at P (which also lies in the osculating plane), of length $1/r$ and pointing toward the center of the osculating circle (called the *center of curvature*). If γ has curvature zero at P, we take **k** to be the zero vector.

We next pass to smooth surfaces embedded in Euclidean three-dimensional space. "Smooth" now means that there is a continuously turning *tangent plane* for each point P of the surface. The tangent plane T at P separates Euclidean three-space into two half-spaces, one of which we arbitrarily consider positive and the other negative. Then we can define a *signed curvature* k to any curve γ through P lying on the given surface Σ which is positive or negative according as the center of curvature of γ at P lies in the positive or negative half-space. (For these signs to vary smoothly with P, we have to *orient* the surface, which can always be done locally—i.e., in a neighborhood of P.)

Consider the line through P that is perpendicular to T, called the *normal line* at P. A plane that contains the normal line intersects the surface in a plane curve. We can imagine this plane rotating around the normal line, and as it does so, it will cut out different curves on the surface passing through P. We have already explained how to define the curvature at P for each of these normal sections. In general, these curvatures will vary as we rotate around the normal line. (In the special case of a sphere these curvatures are constant and equal to the reciprocal of the radius of the sphere, since the curves cut out are all great circles on the sphere.) It can be proved by methods of differential geometry that these curvatures achieve a maximum value k_1 and a minimum value k_2 as we rotate, and the corresponding normal sections (called *principal curves*) are perpendicular to each other. The product

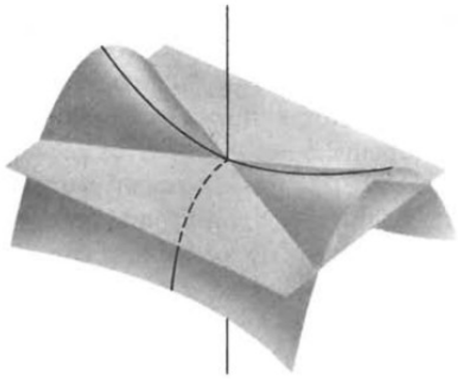

FIGURE A.12

$K = k_1k_2$ of these maximum and minimum curvatures is now called the *Gaussian curvature* (after Gauss, who first studied it), or simply "the curvature," of the surface at the point P. Once again, K will in general change as P varies over the surface; if K happens to stay constant, we obtain the three geometries discussed in Chapter 10, according as K is negative (pseudosphere), zero (plane), or positive (sphere).

In Figure A.12, the tangent plane, normal line, and principal curves for a saddle-shaped surface are shown. For point P on this surface the Gaussian curvature will be a negative number, according to our convention, since the osculating circles for the two principal curves lie on different sides of the tangent plane. On the other hand, for the egg-shaped surface in Figure A.13, the two principal curves lie on the same side of the tangent plane, so the Gaussian curvature is positive.

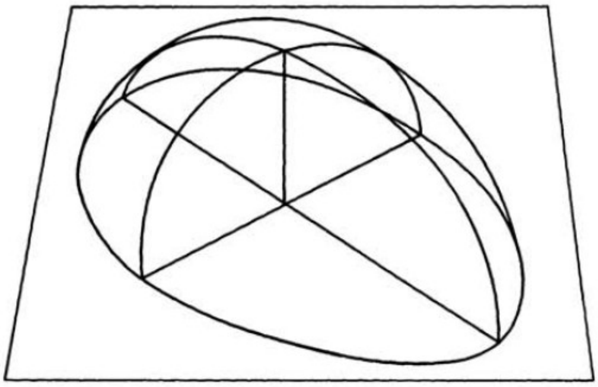

FIGURE A.13

Refer back to the picture of a pseudosphere in Figure 10.12, which is obtained by revolving a tractrix around its asymptote. At any point on this surface, it can be shown that the two principal curves are the (horizontal) circle of revolution through that point and the (vertical) tractrix through that point. Since these curves lie on opposite sides of the tangent plane, we see that the surface curvature is negative. As we move up the surface, the circle shrinks and its curvature increases indefinitely, while the tractrix flattens and its curvature decreases to zero (the curvature of its asymptote); this makes it plausible that the product K of the principal curvatures could stay constant (but of course the proof of that requires a calculation).

Similarly, in the case of a cylinder obtained, say, by rotating a vertical line around a parallel vertical line, the principal curves at any point are the horizontal circle and the vertical line, which has curvature $k_2 = 0$; hence, the Gaussian curvature $K = k_1k_2$ at any point on a cylinder will also be zero (see Figure A.14). We can better grasp this surprising result if we think of a cylinder as a "rolled-up plane." Surely, in any sensible definition of surface curvature a flat plane should be assigned zero curvature. In the process of "rolling-up" a rectangular plane strip the arc lengths and angles between curves on the strip are not changed, and in this sense the "intrinsic geometry" is not changed. Gauss was looking for a definition of surface curvature that depended only on the intrinsic geometry of the surface, not on the particular way the surface was embedded in Euclidean three-space. He was able to prove that his curvature K did not change if the surface was subjected to a "bending" in which arc lengths and angles of all curves on the surface are left invariant. Thus, K describes the intrinsic curvature of the surface independent of the way it is bent to fit into Euclidean three-space. This is all the more remarkable because the principal curvatures k_1 and k_2 may change under such a "bending"; nevertheless, their product $K = k_1k_2$ stays the same. Gauss was so excited about this result that he named it the *theorema egregrium,* "the extraordinary theorem." In a letter to the astronomer Hansen he wrote: "These investigations deeply affect many other things; I would go so far as to say they are involved in the metaphysics of the geometry of space."

Gauss also solved the problem of determining this intrinsic curvature K without reference to the ambient three-space. Imagine a two-dimensional creature living on a surface and having no conception of a

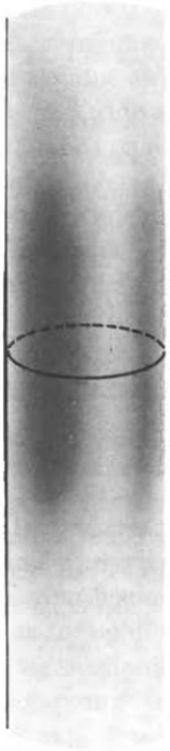

FIGURE A.14 Gaussian curvature of a cylinder is zero.

third dimension, being unable to conceive of the normal lines we used to define the curvature K. How could this creature calculate K? We will have to use the language of the differential calculus to give Gauss' answer.

In the Euclidean plane a point is determined by its x and y coordinates. If these coordinates are subjected to infinitesimal changes denoted dx and dy, then the point moves an infinitesimal distance ds whose square is given by the Pythagorean formula $ds^2 = dx^2 + dy^2$. Now on a smooth surface a point will also be determined locally by two coordinates x and y. If these coordinates are subjected to infinitesimal changes dx and dy, then the point moves a distance ds on the surface whose square is given by the more complicated expression

$$ds^2 = E\,dx^2 + 2F\,dx\,dy + \mathrm{G}\,\mathrm{dy}^2,$$

where E, F, and G may vary as the point varies. The functions E, F and G could in principle be determined by the two-dimensional creature making measurements on his surface. Gauss then showed that his curvature K is given in terms of E, F, and G by a not-too-complicated formula (see Lanczos, 1970, p. 183). Thus, the creature could also calculate K from this formula and discover that his world was curved, although he would have difficulty visualizing what that might mean.

Although this talk about a two-dimensional creature may seem bizarre, it is not, as Riemann demonstrated. Riemann reasoned that we are in an entirely analogous situation, living in a three-dimensional universe in which an infinitesimal change in distance ds is given by an analogous formula involving the three infinitesimals dx, dy, and dz:

$$ds^2 = g_{11}\, dx^2 + g_{22} dy^2 + g_{33} dz^2 + 2g_{23} dy\, dz + 2g_{31} dz\, dx + 2g_{12} dx\, dy.$$

From this formula Riemann was able to define a "curvature tensor" analogous to the Gaussian curvature for a surface, only more complicated: Gauss' curvature involved only a single number K, whereas Riemann's depended on six different numbers. Riemann discovered this curvature almost accidentally in his research on heat transfer. In fact, he developed such a curvature tensor for abstract geometries of any dimension n, and Einstein was able to apply Riemann's ideas to his four-dimensional space-time continuum.

So we are in the same position as that poor two-dimensional creature. We can make measurements to determine the Riemannian curvature of our universe. Astronomers have been performing such measurements. If we find that the Riemannian curvature is not zero, we know that the geometry is not Euclidean. However, this does not mean that our space is embedded in some higher-dimensional physical space in which it is somehow "curved." When we say, loosely, that "space is curved," we mean only that its geometric properties differ from the properties of Euclidean space in a very specific way given by Riemann's formulas.

It was in his 1854 inaugural lecture *Ueber die Hypothesen welche der Geometrie zugrunde liegen* ("On the hypotheses that form the foundation for geometry") that Riemann introduced the idea of an n-dimensional space whose intrinsic geometry is determined by a quadratic formula for the infinitesimal change in distance ds. Such a structure is now called a *Riemannian manifold* (see Spivak, 1970, or Do Carmo, 1976, for the definition). Different manifolds yield different geometries, so that Riemann discovered an infinite number of new geometries.

Let us return to the two-dimensional case of a surface Σ. For each point P on Σ and each curve γ lying on Σ and passing through P, the curvature vector $\mathbf{k}$ decomposes naturally into a vector sum

$$\mathbf{k} = \mathbf{k}_n + \mathbf{k}_g$$

of its projection $\mathbf{k}_n$ on the normal line and its projection $\mathbf{k}_g$ on the tangent plane T to Σ at P; these projections are called, respectively, the *normal* and *tangential curvature vectors.* The length of $\mathbf{k}_g$ is called the *geodesic curvature* k_g of the curve γ at P relative to Σ. We call γ a *geodesic* if $k_g = 0$. In that case, γ has *zero curvature relative to the surface* Σ; it may have nonzero curvature relative to Euclidean three-space, but then its curvature vector points along the normal line to the surface at P. Another way to describe a geodesic γ that has nonzero $\mathbf{k} = \mathbf{k}_n$ is that its osculating plane Π at P is perpendicular to the tangent plane T (since Π contains the normal line at P). From this description we see immediately that the geodesics on a sphere are its great circles ($\Pi \perp T$ iff Π passes through the center of the sphere); Figure A.15.

This description of geodesic curvature refers to the ambient Euclidean three-space. But F. Minding in 1830 showed that it too is an intrinsic quantity for Σ: it depends only on the functions E, F, and G and the curve γ. Hence the notion of "geodesic" can be defined on a Riemannian manifold. And it gives us the correct interpretation of the heretofore confusing term *straight line* on such a manifold. Riemann recognized that the geodesics would be of finite length if the curvature of the surface was greater than some positive constant.

A proposed alternative interpretation of the term "straight line

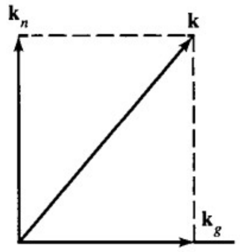

FIGURE A.15

segment" is "the shortest path on the surface joining two points on the surface." It can be proved that *if such a shortest path exists, it must be an arc of a geodesic.* But a shortest path may not exist: let Σ be a punctured plane or a punctured sphere; two points on opposite sides of the puncture cannot be joined by a shortest path on Σ. On *complete* manifolds (meaning that every Cauchy sequence of points converges), it can be proved that shortest paths always exist (theorem of Hopf-Rinow). However, an arc of a geodesic need not be the shortest path: consider the longer great-circular arc joining two nonantipodal points on a sphere, or consider the helical arc joining two points on a vertical line on the cylinder in Figure A.16. So the definition of "geodesic" (found in several books by nonmathematicians) as "the shortest path" is inadequate because it excludes such arcs.

It is important to note that, although we have emphasized Riemann's generalization of Gauss' ideas from two dimensions to higher dimensions, Riemann's formulation gives new information about *surfaces* that cannot be embedded in Euclidean three-space. For example, the hyperbolic plane can be described as a complete two-dimensional Riemannian manifold of constant negative curvature, and the elliptic plane can be described as a complete two-dimensional Riemannian manifold of constant positive curvature on which any two points lie on a unique geodesic. Neither of these manifolds can be analytically embedded in Euclidean three-space.

Some idea of Riemann's influence on modern mathematics can be gleaned from the following list of concepts, methods, and theorems

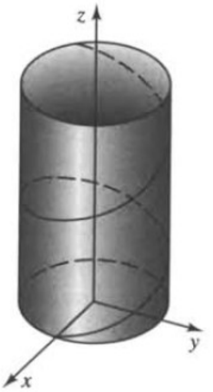

FIGURE A.16 A helix is a geodesic on a cylinder.

that have been named after him: Riemannian curvature of Riemannian manifolds, Riemann integral, Riemann-Lebesgue lemma, Riemann surfaces, Riemann-Roch theorem, Riemann matrices, Riemann hypothesis about the Riemann zeta function, Riemann's method in the theory of trigonometrical series, Riemann's method for hyperbolic partial differential equations, Riemann mapping theorem, and Cauchy-Riemann equations.[2]

---

APPENDIX B
GEOMETRY WITHOUT CONTINUITY

> Any serious student should become familiar with the great discovery, made at the end of the last century, that large parts of geometry do not depend on continuity.
>
> H. BUSEMANN AND P. J. KELLY

If Euclid could have returned to life at the beginning of the twentieth century and heard the criticisms made of the gaps in his work, he undoubtedly would have accepted the incidence, betweenness, and congruence axioms that replaced his first four postulates. A model of those axioms is called an H-*plane* ("H" for Hilbert, Hessenberg, and Hjelmslev). However, it is easy to imagine Euclid bristling at Dedekind's continuity axiom, although he could be expected to admit Archimedes' axiom and the elementary continuity principle.

Much work has been done in the last century to develop geometries without continuity assumptions. The most comprehensive such treatise is F. Bachmann's *Aufbau der Geometrie aus dem Spiegelungsbegriff* (Construction of Geometry based on the Concept of Reflection, 1973), in which plane geometries based only on axioms of incidence, perpendicularity, and reflections are studied.[1] Bachmann is justified in calling this study *plane absolute geometry,* since it includes elliptic, hyperbolic, and Euclidean geometries as special cases (as well as other unusual geometries). Bachmann has succeeded in dispensing with betweenness axioms as well as continuity axioms. It is unfortunate that he calls models of his axioms "metric" planes—since "metric spaces" have a quite different meaning in which a "metric" measures distance by real numbers; I propose calling them *absolute planes.*

---

[1] For a presentation of Bachmann's axioms in English, see Ewald (1971). I. M. Yaglom, in the foreword to the Russian translation of Bachmann's book, calls it "indisputably the most significant development in the foundations of geometry in decades." You were introduced to Bachmann's methods on pp. 340–342 and in Exercise 50 of Chapter 9.

The key ideas for this study are:

1. Embed the absolute plane in a projective plane.
2. Show that the points and lines in this projective plane have homogeneous coordinates from some field K (as in Major Exercise 10, Chapter 2).
3. Show that two lines are perpendicular if and only if their coordinates satisfy a particular homogeneous quadratic equation.
4. Use algebra to get further information about the absolute plane.

This program has been completely successful in classifying H-planes (the problem of determining all absolute planes remains unsolved). In particular, it is shown that (up to isomorphism) the only H-planes in which Archimedes' axiom and the elementary continuity principle hold are either the Cartesian model or the Klein model over an Archimedean Euclidean field K (Archimedean ordered field in which every positive element has a square root). This result is particularly remarkable because it gives the existence of limiting parallel rays in the non-Euclidean case without appealing to Dedekind's continuity axiom (compare the proof of Theorem 6.6, p. 196).

Let us describe the embedding briefly. The intuitive idea comes from our discussion of the Klein model, in which new "ideal" and "ultra-ideal" points are introduced so that lines that were previously parallel now meet when extended through these new points (see Major Exercise 13, Chapter 6, and p. 240). Abstractly, the new points are simply pencils of lines. The old points are in one-to-one correspondence with the pencils of the first kind, i.e., A corresponds to the pencil p(A) of all lines through A.

An ultra-ideal point is a pencil of the second kind; it is a pole P(t), which for a fixed line t consists of all the perpendiculars to t. But the pencils of the third kind must be described carefully to avoid circular reasoning. We described such a pencil in Chapter 9 (p. 340) as consisting of all lines through a fixed ideal point, the ideal point being defined as an equivalence class of limiting parallel rays. Since we don't know limiting parallel rays exist now, we instead use the theorem on three reflections (Proposition 9.19) as our definition: the pencil $p(lm)$ determined by parallel lines l and m which do not have a common perpendicular consists of all lines n such that the product

$$R_l R_m R_n$$

is a reflection. Certain properties that were previously obvious now require a considerable amount of ingenuity to prove — for example, if $h, k \in p(lm)$, then $p(hk) = p(lm)$. Hjelmslev discovered how to prove that a pencil of the first kind $p(\text{D})$ and a pencil of the third kind $p(a'c')$ have a unique line b in common (see Figure B.1). He dropped perpendiculars a, c from D to a', c' at points A, C, then dropped perpendicular d from D to $\overleftrightarrow{AC}$. Then the line b is uniquely determined by the equation

$$R_a R_b R_c = R_d.$$

We now know the new points of our projective plane. Our old lines a can be extended to new lines $l(a)$ so that any pencil containing a is by definition incident with $l(a)$. But we need more new lines to fill out our projective plane. For example, for any old point A, the polar $l(\text{A})$, consisting of all poles of lines through A, should be a new line; in the Klein model, this line lies entirely outside the absolute circle (in the Cartesian model, it's the line at infinity); see Figure B.2.

But how are we to describe the lines in the Klein model that are tangent to the absolute circle, and how are we to verify the axioms for a projective plane? To accomplish this, Hjelmslev discovered a remarkable device: he fixed a point O and fixed a pair u, v of nonperpendicu-

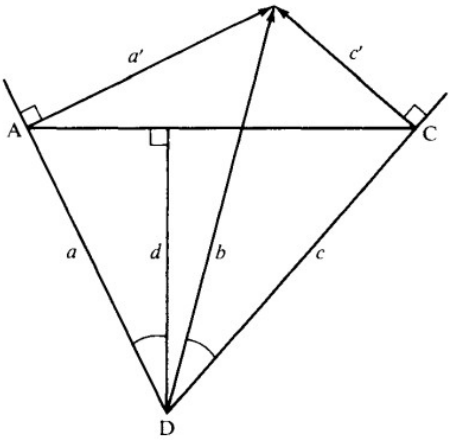

FIGURE B.1

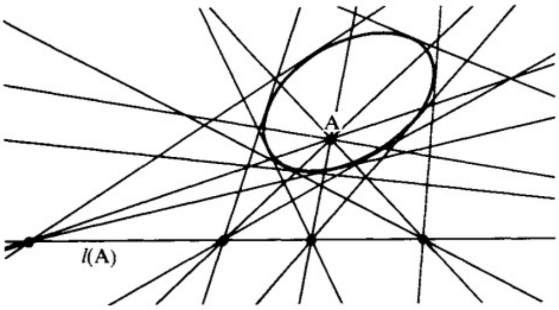

FIGURE B.2 The polar of a point.

lar lines through O — think of these lines as determining an acute angle θ. He then defined a transformation that fixed O and sent any $A \neq O$ to the midpoint A^* of the segment joining A to its image under rotation $R_u R_v$ about O through angle 2θ (Figure B.3); this transformation is called the *half-rotation* (or *snail map*) about O corresponding to u, v.

Hjelmslev observed that in the Klein model, half-rotations extend to collineations of the projective plane, and that any projective line except $l(O)$ could be mapped onto an extended Klein line $l(a)$ by a suitable half-rotation about O. So he proposed to call a set of pencils a "line" if it is mapped onto some $l(a)$ by some half-rotation about O, or if it is $l(O)$. With this definition, he was then able to verify the axioms for a projective plane.

The execution of idea 2 — construction of the field K of coordinates — requires even more technique. The key tool is a complicated theorem of Hessenberg, which generalizes the Euclidean theorem that tells when a quadrilateral can be circumscribed by a

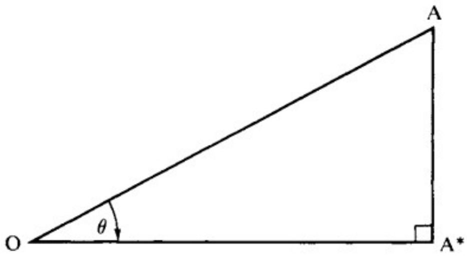

FIGURE B.3

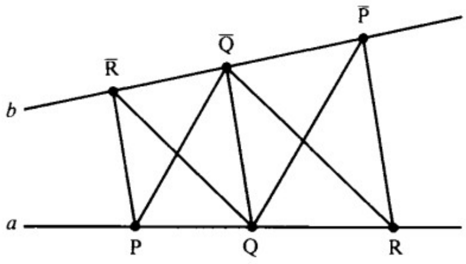

FIGURE B.4 Pappus' theorem.

circle. The method of constructing K is the standard method for any affine plane in which Pappus' theorem holds (Ewald, 1971, Chapter 3); here the affine plane is obtained by removing the polar $l(\mathrm{O})$ of O, and Pappus' theorem states: Let P, Q, R lie on a, $\overline{\mathrm{P}}$, $\overline{\mathrm{Q}}$, $\overline{\mathrm{R}}$ lie on b, such that a does not meet b in any of these six points (Figure B.4). If $\mathrm{P}\overline{\mathrm{Q}} \parallel \overline{\mathrm{P}}\mathrm{Q}$ and $\mathrm{Q}\overline{\mathrm{R}} \parallel \overline{\mathrm{Q}}\mathrm{R}$, then $\mathrm{P}\overline{\mathrm{R}} \parallel \overline{\mathrm{P}}\mathrm{R}$. Bachmann's approach is to verify Pappus' theorem by brute force; there is another approach due to Lingenberg that I believe gives more insight (see Lenz, 1967, p. 206 ff., on the Euclidean "pseudoplane"). Pappus' theorem implies that the definition given for "lines" in our projective plane does not depend on the choice of O.

If we started with an H-plane, it is then possible to define an order on K in terms of the betweenness relation in the H-plane. We need only specify the set P of positive scalars (since $x < y \Leftrightarrow y - x > 0$).

Choose any two points A, B from the H-plane. For any third point X collinear with A, B, the ratio

$$\mathrm{AX}:\mathrm{BX}$$

is defined to be that unique scalar in K which, multiplying the vector from B to X, gives the vector from A to X. We then define P to consist of 1 and all ratios AX : BX as X runs over all third points on the affine line $\overleftrightarrow{\mathrm{AB}}$ that do *not* lie between A and B (this includes all ideal and ultra-ideal points on $\overleftrightarrow{\mathrm{AB}}$). It can be shown from invariance of the ratio under parallel projection that this definition of P does not depend on the choice of A, B.

Moreover, a theorem of Menelaus (compare Exercise H-5, Chapter 7) can be proved for these ratios, and can be used to demonstrate that P has all the properties required for a set of positive numbers that makes K an *ordered field* (see Lenz, 1967, p. 223 ff.). In turn, this enables us to extend the betweenness relation to all triples of collinear points in the affine plane, and to show that the H-plane is embedded as a convex open subset of the affine plane, containing the origin O. The embedding is locally Euclidean at O in that perpendicularity for lines through O has the familiar meaning from Cartesian analytic geometry.

It can be proved (from free mobility—Lemma 9.3, p. 358) that the field K is Pythagorean (the sum of two squares is a square), but K is not Euclidean unless the elementary continuity principle holds (a neat algebraic criterion for this geometric property).

As for idea 3 on our list, further argument shows that there is a constant $k \in K$ such that lines having homogeneous coordinates $[a_1, a_2, a_3]$, $[b_1, b_2, b_3]$ are perpendicular if and only if

$$a_1b_1 + a_2b_2 + ka_3b_3 = 0.$$

Here "perpendicularity" has been extended to all pairs of lines in the projective plane, and there may exist certain lines (called *isotropic*) that are perpendicular to themselves (e.g., when $k = -1$, the line $[0, 1, -1]$, i.e., $y = 1$). To each line $[a_1, a_2, a_3]$ is associated its *pole* $[a_1, a_2, ka_3]$ (except for line at infinity $[0, 0, 1]$ when $k = 0$), and we see that the perpendiculars to this line are precisely the lines passing through its pole; isotropic lines pass through their own poles, and for $k \neq 0$, the locus of poles of isotropic lines is given by the affine equation

$$x^2 + y^2 = -k^{-1}$$

and may be called *the absolute*. The points (x, y) in the H-plane satisfy the inequality $|k|\,(x^2 + y^2) < 1$.

The fourth angle of a Lambert quadrilateral is acute, right, or obtuse accordingly as $k < 0$, $k = 0$, or $k > 0$. If $k = 0$ and the H-plane fills up the affine plane, we obtain the *generalized Euclidean plane* over K. However, if $k = 0$, if K is non-Archimedean, and if we restrict our H-plane points to those (x, y) that are infinitesimal, we obtain Dehn's *semi-Euclidean plane*, in which the Euclidean parallel postulate fails but rectangles exist.

If $k = -1$, the absolute is the unit circle, and if every point in its interior belongs to the H-plane, we obtain the *generalized hyperbolic plane* over K, provided K is Euclidean. In case K is non-Archimedean, we can again restrict (x, y) to infinitesimal values, obtaining Schur's *semihyperbolic plane,* in which limiting parallel rays do not exist, even though the elementary continuity principle holds (the ideal points fill up an entire region inside and on the absolute).

If neither k nor $-k$ is a square (so K is not Euclidean), yet every sum $1 + kx^2$ is either a square or k times a square, the points (x, y) satisfying $x^2 + y^2 < |k^{-1}|$ form a *semielliptic* H-plane, in which parallel lines have a unique common perpendicular (the absolute is empty).

Finally, if K is non-Archimedean, $k = 1$, and (x, y) are again restricted to infinitesimal values, we obtain Dehn's *non-Legendrian plane,* in which the fourth angle of a Lambert quadrilateral is obtuse.

You can see that there are some unusual H-planes, most of them living on non-Archimedean fields; on Archimedean fields, only Euclidean, hyperbolic, and semielliptic planes survive. For the complete algebraic classification of H-planes (discovered by W. Pejas, 1960), see Hessenberg and Diller (1967). For an introduction to absolute plane geometry in English, see Chapter 5 of Bachmann, Behnke, and Fladt (1974). Finally, for an expanded version of this appendix, see my article "Euclidean and Non-Euclidean Geometries without Continuity," *American Mathematical Monthly,* November 1979.

by Axiom 5 and hypothesis $B*Y*P$ and $B*P*A$, then by Theorem 7 $B*Y*P*A$ and, hence, $B*Y*A$. By Axiom 5 $A*Y*B$. ●

We shall certainly want a point on a segment to "divide" the segment into two parts. We can now prove a theorem analagous to Theorem 12.

Theorem 21. Any point P on a segment $A\text{–}B$ separates $A\text{–}B$ into two nonempty subsets $A\text{–}P$, $P\text{–}B$ which together with P form a partition of $A\text{–}B$.

Proof: By Theorems 16 and 20 $A\text{–}P$, $P\text{–}B$ are nonempty and subsets.

(a) Partition: Let P be any point on $A\text{–}B$ and $X \neq P$ any point on $A\text{–}B$. We want to show that X is an element of one and only one of the subsets $A\text{–}P$, $P\text{–}B$. By Theorem 18 we are permitted to apply Axiom 8. By Axiom 8, if $A*P*B$ then $A*P*B*X$, $A*P*X*B$, $A*X*P*B$, or $X*A*P*B$. But since $A*X*B$ we have $A*P*X*B$ or $A*X*P*B$ but not both. Thus, for any point X either $P*X*B$ or $A*X*P$ but not both; hence, any point X of $A\text{–}B$ is on one and only one of the sets $A\text{–}P$, $P\text{–}B$. Therefore, $A\text{–}P$, $P\text{–}B$ together with P (Theorem 15) form a partition of $A\text{–}B$.

(b) Separation: Now let X_1, Y_1 be two distinct elements of set $A\text{–}P$. Then $A*X_1*P$ and $A*Y_1*P$. By Axiom 5 we may write $P*X_1*A$ and $P*Y_1*A$, from which it follows by Theorem 10a that $P*X_1*Y_1$ or $P*Y_1*X_1$; therefore it follows from Axiom 7 that X_1*P*Y_1 cannot hold. Similarly for X_2, Y_2 as elements of $P\text{–}B$.

Suppose now that X_1, X_2 are any two elements, one from each set; it follows from part (a) that they are distinct. We want to show that X_1*P*X_2. $A*X_1*P$ and $A*P*B$ imply $A*X_1*P*B$ and, hence X_1*P*B. X_1*P*B and $P*X_2*B$ imply X_1*P*X_2*B; hence X_1*P*X_2. ●

EXERCISES 5.3

1–5. Prove Theorems 15–19. (*Theorem 19)

*6. Prove that a segment has an infinite number of points. (Hint: by contradiction; if not, there must exist an empty segment.)

7. Prove that a line has an infinite number of points.

5.4 The Axiom of Pasch

In many standard proofs of high-school geometry, lines through a vertex of a triangle are considered—angle bisectors, for example, as illustrated in Figure 5.7. In all such cases it is *assumed* that these lines intersect the opposite side of the triangle, but on what basis is such an assumption

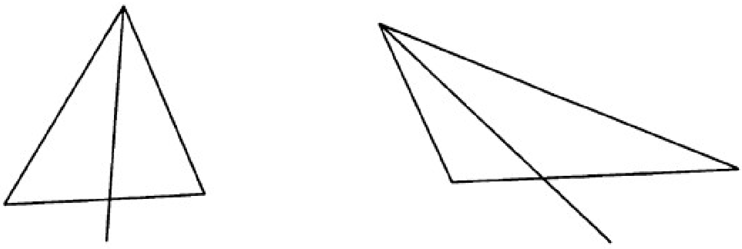

FIGURE 5.7

justified? Pasch, in the late nineteenth century, is credited with first maintaining not only that such a statement needs justification but that it is impossible to prove from the standard Euclidean axioms. So he introduced the following axiom, which is illustrated in Figure 5.8.

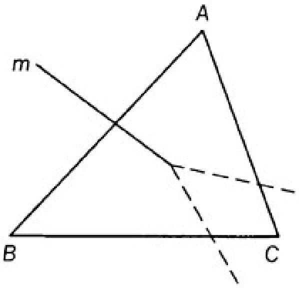

FIGURE 5.8

Axiom 10. ***(Pasch)*** If A, B, C are three distinct and noncollinear points, m is a line not passing through any of them, and m contains a point of segment $A\text{–}B$, then m also contains a point of segment $A\text{–}C$ or $B\text{–}C$.

This axiom does not immediately solve the problem about angle bisectors; before we can solve such a problem we must first be able to state it precisely. Note, as in Figure 5.9, that not every line through a

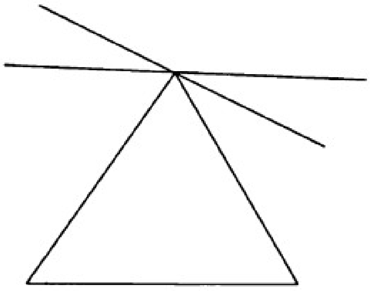

FIGURE 5.9

vertex of a triangle passes through the opposite side; it must also pass through a point *inside* the triangle.

In order to express and prove such a theorem we shall want definitions of "triangle" and "inside," as well as some related theorems. Thus we shall postpone some of this until we have established the groundwork. Let us start with a theorem that shows that the alternative expressed in Pasch's axiom is an exclusive one. See Figure 5.10.

Theorem 22. If A, B, C are noncollinear points, any line m containing a point of segment A–B, and a point of segment A–C, cannot contain a point of segment B–C.

Proof: Suppose that there exists a line m with three such points; that is, a line with points D, E, and F such that D belongs to A–B, E belongs to B–C, and F belongs to A–C. By Axiom 7 one point, say F on A–C must lie between the others, so $D{*}F{*}E$. Since E is contained in B–C, it is contained in line BC—this follows from Theorem 18. Similarly, D is contained in line AB. It follows, therefore, that D, E, and B are noncollinear, for otherwise Theorem 4 is contradicted. (Why)? Thus by Axiom 10 the line AC which intersects D–E at F must intersect either B–E or B–D. But by Theorem 4 and Axiom 7 this is impossible. Hence, the assumption is false. The argument proceeds similarly if $D{*}E{*}F$ or $F{*}D{*}E$. ●

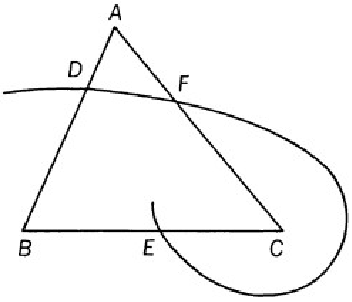

FIGURE 5.10

We might have introduced the following definition at the beginning of the section. By postponing it until now, we have shown merely that this definition is unnecessary; we now hope to show that it helps us to make statements more succinctly, clearly, and in keeping with our intuition.

Definition 8. Given three distinct noncollinear points A, B, C, the new set which is the union of A, B, C together with A–B, A–C, and B–C, is called a *triangle*, and:

A, B, C are called the *vertices;* each one a *vertex.*
A–B, A–C, B–C are called the *sides.*
The lines containing the sides are called the *sidelines.*

Because of Theorems 17 and 19 and the above definition we may state the following rules:

Language Rule 9: *A triangle is* DETERMINED *by its vertices.*

Notation Rule 8: *The triangle determined by A, B, C will be denoted by:*

$$\triangle ABC$$

We shall read this and often denote it "triangle ABC."

It should be noted that because endpoints are not parts of segments, vertices are not parts of sides of triangles.

We may now state Axiom 10 in the simpler form:

If a line not through a vertex intersects one side of a triangle, it intersects at least one of the other sides.

Theorem 22 may be restated in either of the following more intuitive forms:

If a line intersects one side of a triangle, it intersects at most one of the other sides.

A line cannot intersect all three sides of a triangle.

The machinery has now been built to enable us to prove a very important theorem. But first we shall want a definition and two preliminary theorems:

Definition 9. Let m be any line and P a point not on it. Let S_1 be the set of all points consisting of P and all points X not on m such that P–X contains no point of m. Let S_2 be the set of all points Y, such that P–Y contains a point of m. Then S_1, S_2 are called *half planes of line m.*

Theorem 23. Half planes of a line m are nonempty.

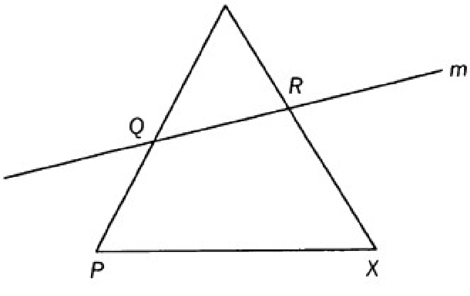

FIGURE 5.11

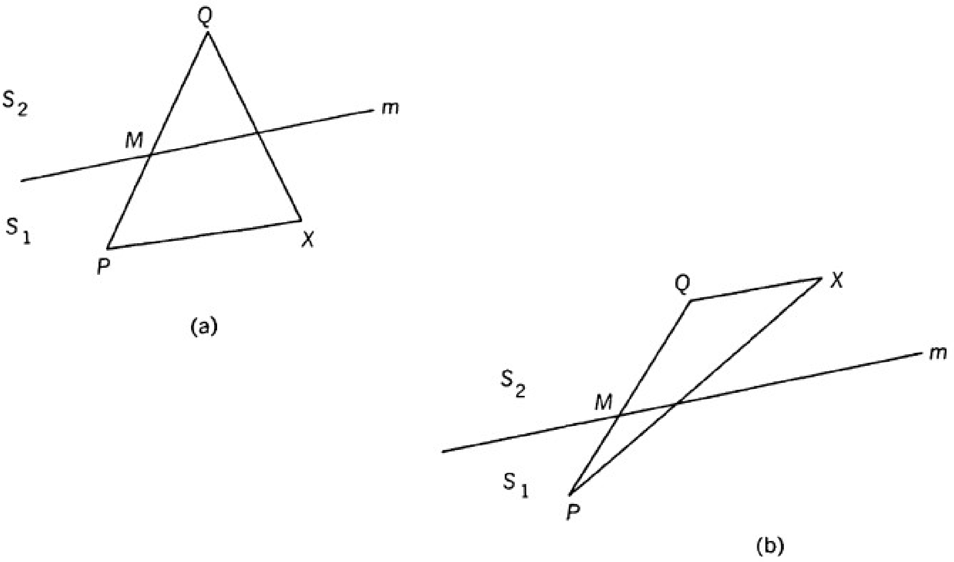
Proof: Given a line m, there exists a point P not on m and a point Q on m. There exists a point Y such that $P*Q*Y$ and, hence, P–Y contains a point of m. There exists another point R on m and a point X such that $Y*R*X$. Then by Theorem 22 m cannot contain a point of P–X. ●

Theorem 24. There exist exactly two half planes of a line m (relative to a point P) which together with m form a partition of the set of all points.

Proof: Every point is either on m or not. No point is both. Consider the points not on m. By the argument of Theorem 23, if M is a point of m, then there exist points P, Q not on m and such that $P*M*Q$. Let X be any point not on m. If X is collinear with P and Q, then exactly one of the following holds: $X*P*Q$, $P*X*Q$, $P*Q*X$, $X = P$ or $X = Q$. Then exactly one of the segments Q–X, P–X meets m. (Proof in the first three cases is nontrivial and is left as an exercise.) If X is not collinear with P and Q, then once again exactly one of the segments Q–X, P–X meets m.



(a)

(b)

FIGURE 5.12

For if neither meets m, then since $P*M*Q$, Axiom 10 is contradicted. If both P–X, Q–X meet m, then Theorem 22 is contradicted. Thus, if P–X does not meet m, X is in S_1 as given in Definition 9; and if Q–X does not meet m, then P–X does and X is in S_2 as given in Definition 9. Since these are the only possibilities and each point is in exactly one of the sets m, S_1, S_2 the theorem is proved. ●

It is now possible to prove one of the basic theorems of the foundations of Euclidean geometry. It is often assumed as an axiom (in place of

Pasch's) and called *The Plane Separation Postulate:* any line separates the set of all points into two half planes. To understand the proof, however, it may be necessary to review the meaning of "separates."

Definition 5 is stated in terms of any set S separating two others, S_1 and S_2. S_1 and S_2 must be distinct nonempty disjoint sets which are disjoint from S and are such that two conditions hold: if A is an element of S_1 and B is an element of S_2 there exists a point of S between them; conversely, if there exists a point of S between A and B, they must belong to distinct sets. The converse, if stated in contrapositive form, says: if A and B belong to the same set, there does not exist a point of S between them.

Theorems 23 and 24 show that half planes of a line m, together with m, satisfy the properties of S_1, S_2, and S of the definition. It must now be shown that they satisfy case (a) and case (b) of Definition 5.

Theorem 25. Any line m *separates* the set of all points into two half planes.

Proof: By Theorems 23 and 24 we know that the half planes are nonempty sets disjoint from each other and m. Let P be a point of one half plane, and let A, A' be any two points not on m such that A–P, A'–P contain no point of m. Let B, B' be any two points of the other half plane; that is, not on m but such that P–B, P–B' do contain a point of m.

Case a. If any 3, 4, or 5 of the points P, A, A', B', B are collinear, then it follows that m intersects A–B, A'–B', A'–B, A–B'. (Proof left as an exercise.) If no three of the points are collinear, then it follows directly from Axiom 10 that m intersects A–B, A'–B', A'–B, A–B'.

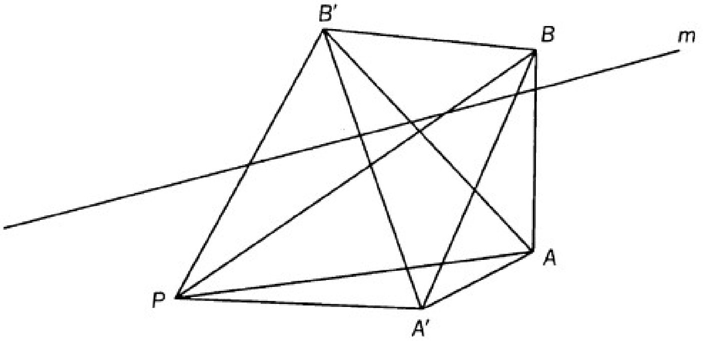


FIGURE 5.13

Case b. The converse says that if A–B intersects m, then A, B belong to different half planes of m. In its contrapositive form, this says that if A, A' belong to the same set, then A–A' does not intersect m. If either A, P, A' are collinear, or B, P, B' are collinear, then it follows that neither

A–A' nor B–B' intersect m. (Proof left as an exercise.) If A, P, A' are not collinear, then since by hypothesis neither P–A nor P–A' intersect m, it follows that Axiom 10 would be contradicted if m intersected A–A'. If B, P, B' are not collinear, then since by hypothesis P–B and P–B' each intersect m, by Theorem 22 m does not intersect B–B'. ●

Language Rule 10: *The sets S_1, S_2 in Definition 9 are said to be* DETERMINED BY m AND P.

The following theorem establishes the uniqueness of half planes determined by a line m and any point not on it.

Theorem 26. Let m be a line, P, P' two points not on m. The half planes determined by m, P are the same as those determined by m and P'.

Proof: Left as an exercise.

Theorem 27. Let m, m' be distinct lines. The half planes of line m are distinct from the half planes of line m'.

Proof: Left as an exercise.

EXERCISES 5.4

1. Complete Theorem 24.
2. Complete Theorem 25.
*3. Prove Theorem 26.
4. Prove Theorem 27.
5. Prove that if $A*F*B$, and $B*C*D$, then there exists a point E on F–D such that $A*E*C$. A, B, C are noncollinear.
6. Prove that if A, B, C are three distinct noncollinear points and D, E points such that $B*C*D$, and $C*E*A$, then there exists a point F on line DE such that $A*F*B$.
7. In exercise 6, show that $D*E*F$.
*8. If in a $\triangle ABC$, $A*D*B$, $A*E*C$, and $B*F*C$, then A–F meets D–E.
9. Prove that in $\triangle ABC$, if $A*D*B$, $B*E*C$, then A–E and C–D intersect.

5.5 Convex Sets

Definition 10. A set S is called a *convex set* if and only if for any two points P, Q, belonging to S, the entire segment P–Q is contained in S.

Theorem 28.

(a) Every line is a convex set.
(b) Each half line of a point O is a convex set.

Non-Euclidean Geometry

introduction

> That, if a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which are the angles less than the two right angles.[1]

Euclid presented this statement as his fifth postulate (axiom) and thereby profoundly influenced the course of mathematical history. Although historians disagree about the authenticity of many parts of the *Elements*, they usually agree that this statement originated with Euclid. That he placed it among his assumptions rather than introducing it as a theorem must be considered a monument to his genius.

It is possible that outside of this text the reader has never before seen this statement and is, therefore, somewhat confused as to how or why it is such an important one. It may help if we say that this statement is known as Euclid's Parallel Postulate; on the other hand, this may cause more bewilderment, for most readers undoubtedly conceive of a parallel axiom along such lines as: through a point not on a given line exactly one line exists parallel to the given line. Indeed, it turns out that this statement is equivalent to the one quoted above. But had Euclid made his statement in the more familiar form it might never have played such an important historical role.

---

[1] Whenever we wish to refer to this particular statement we shall call it the *Parallel Postulate*, or the *Fifth*.

It should be remembered that at the time of Euclid and for centuries thereafter a postulate was regarded not merely as a truth but as a self-evident truth, a truth beyond doubt. Even today this notion is widely held, as indicated by the definitions found in any standard dictionary and by the fact that many people still regard mathematics as the absolute science. This opinion was held all the more firmly in ancient times, and thus incited attacks upon the Fifth.

A look at the other postulates[2] of the *Elements* helps one to understand why the Fifth might cause such furor. Not only is it much more complicated, not only is it not self-evident, it is actually open to doubt.

It was argued that the truth of the Fifth is, at best, merely plausible. For, the arguments continued, is it not true that there exist "lines" which are asymptotic—as in the hyperbola and conchoid? And does not the fact that some lines exist which, though converging, do not meet no matter how far extended make it open to question whether the same might not be true of straight lines? If so, if open to question, then the statement cannot be a postulate.

Centuries of trying to prove the Fifth from the other postulates followed. These attempts led to the development of new geometries and to an entirely new and vastly richer approach to mathematics in general. Exactly how this came about, and a discussion of some of the results, will be the subject of the rest of the text.

---

[2] See Appendix, pp. 218–219.

9 The Concept of Parallelism

In discussing some of the attempts to prove Euclid's fifth postulate we shall learn that there are many statements equivalent to the Fifth. A survey of a list of such statements should convince the reader that the Parallel Postulate is rich in implications. He may wonder, therefore, what would occur if such a statement were discarded or negated. What would happen if we introduced a new parallel postulate? This will be seen in this chapter.

9.1 History

Although we shall not review the entire history of attempts to prove the Fifth,[1] it is necessary to discuss some of these attempts in order to learn how they have led to new discoveries. It is hoped that the following presentation will provide some answers and induce the reader to seek out others.

Proclus ***(410–485*** A.D.)

Proclus is the source of much of the knowledge we have about Euclid and his earliest critics and commentators. According to Proclus, the first attempts to prove the Parallel Postulate began almost immediately and were coordinated with revised statements of Euclid's definition of *parallel*. One should not confuse the postulate with his twenty-third definition:

---

[1] For a more complete history, see R. Bonola, *Non-Euclidean Geometry*, translated by H. S. Carslaw (Open Court Publishing Company, 1912).

Parallel straight lines are straight lines which, being in the same plane and being produced indefinitely in both directions, do not meet one another in either direction.

Of the many attempts listed by Proclus, the most significant involves changing this definition of parallel lines to: parallel lines are lines which are everywhere equidistant. How this is then used to attempt to prove the Fifth need not be discussed. For Proclus was the first to point out that there *might* exist parallel lines in Euclid's sense that are not everywhere equidistant. Thus, to use his definition, it would be necessary to prove first that if two straight lines do not meet they are equidistant. And to do this requires the Fifth Postulate or a statement equivalent to it.

As is often the case, the good critic is not necessarily an innovator. The barbs Proclus throws at the attempts of others are sharp and well-directed; but, when he tries a proof of his own, he falls equally short of success.

First, he argues that the Fifth cannot be an axiom. His reasoning, if accurately recorded, must be taken as evidence of how distorted man's thinking can become when he is obsessed with proving a point. Proclus argues, correctly, that Proposition 17 of the *Elements* is the converse of the Fifth; but he then says that it is impossible that a statement whose converse can be proved is not capable itself of being proved!(!)(!)

With reasoning such as this to justify his attempt, he then proves the Fifth by assuming a statement equivalent to it, namely, that parallel lines remain a finite distance apart.

It is for this type of argument that Proclus criticizes all others who had attempted a proof. In each case he points out that, to prove the postulate, either an assumption equivalent to it or some paradoxical assumption about infinite areas and lengths behaving like finite ones has been made. This criticism applies equally well to most later attempts.

Through the ages, in the many attempts to prove the Parallel Postulate, a long list of statements equivalent to it has been gathered. Most of the important ones were known to Proclus. Among them are the following:

1. There exist straight lines everywhere equidistant from one another.
2. If a straight line intersects one of two parallels, it will intersect the other.
3. Straight lines parallel to the same straight line are parallel to one another.
4. The sum of the angles of a triangle is equal to two right angles.
5. Two straight lines which intersect one another cannot both be parallel to the same line.

> Parallel straight lines are straight lines which, being in the same plane and being produced indefinitely in both directions, do not meet one another in either direction.

Of the many attempts listed by Proclus, the most significant involves changing this definition of parallel lines to: parallel lines are lines which are everywhere equidistant. How this is then used to attempt to prove the Fifth need not be discussed. For Proclus was the first to point out that there *might* exist parallel lines in Euclid's sense that are not everywhere equidistant. Thus, to use his definition, it would be necessary to prove first that if two straight lines do not meet they are equidistant. And to do this requires the Fifth Postulate or a statement equivalent to it.

As is often the case, the good critic is not necessarily an innovator. The barbs Proclus throws at the attempts of others are sharp and well-directed; but, when he tries a proof of his own, he falls equally short of success.

First, he argues that the Fifth cannot be an axiom. His reasoning, if accurately recorded, must be taken as evidence of how distorted man's thinking can become when he is obsessed with proving a point. Proclus argues, correctly, that Proposition 17 of the *Elements* is the converse of the Fifth; but he then says that it is impossible that a statement whose converse can be proved is not capable itself of being proved!(!)(!)

With reasoning such as this to justify his attempt, he then proves the Fifth by assuming a statement equivalent to it, namely, that parallel lines remain a finite distance apart.

It is for this type of argument that Proclus criticizes all others who had attempted a proof. In each case he points out that, to prove the postulate, either an assumption equivalent to it or some paradoxical assumption about infinite areas and lengths behaving like finite ones has been made. This criticism applies equally well to most later attempts.

Through the ages, in the many attempts to prove the Parallel Postulate, a long list of statements equivalent to it has been gathered. Most of the important ones were known to Proclus. Among them are the following:

1. There exist straight lines everywhere equidistant from one another.
2. If a straight line intersects one of two parallels, it will intersect the other.
3. Straight lines parallel to the same straight line are parallel to one another.
4. The sum of the angles of a triangle is equal to two right angles.
5. Two straight lines which intersect one another cannot both be parallel to the same line.

6. Through a given point not on a given line only one line can exist parallel to the given line.

Statement (6) is probably the form in which most readers have encountered the parallel postulate. Although known to Proclus, it is called "Playfair's Axiom" after a British geometer of the eighteenth century.

When we say that these statements are each equivalent to the Fifth we mean that they (together with other assumptions) mutually imply each other. That the Parallel Postulate implies each of these statements is evident to anyone who has studied the *Elements*, for these statements are either proved there as theorems or follow quite directly from theorems that are proved. That each of these statements in turn imply the Fifth has been shown at various times by many mathematicians; some of the proofs are quite complicated, but this should come as no surprise since, after all, it requires thirty theorems before Euclid proves any of them from the Fifth.

If we were merely attempting to prove the Parallel Postulate as a theorem in some system, there would be nothing wrong with using any of these equivalent assumptions in proving the Fifth. Because we are attempting to prove the Parallel Postulate from the other four postulates of Euclid, care must be taken. Suppose, for example, that we use the fact that the sum of the angles of a triangle is equal to two right angles to prove the Fifth, and suppose the proof is correct. The problem with such a course lies in determining whether or not the assumed statement about the sum of the angles is a true statement. It is either an axiom or a theorem. To take it as an axiom defeats the purpose of the undertaking. To take it as a theorem involves one in a circularity problem, for the only way to prove it is to use the Fifth or a statement equivalent to it.

Gerolamo Saccheri (1667–1733)

During the centuries that followed Proclus, countless other attempts were made to prove the Parallel Postulate and numerous new flaws and equivalent statements were uncovered. We shall pass over these attempts until we come to Gerolamo Saccheri, an Italian mathematician of the seventeenth and eighteenth centuries, who came up with a new approach.

Saccheri assumes the first four postulates, all the theorems proved from them (the first 28), and assumes that the Fifth is false. In other words, he attempts to prove the truth of the postulate by the indirect method.

As a basic figure in his work, he takes a quadrilateral $ABCD$, with right angles at A and B, and $A\text{–}D \cong B\text{–}C$. He then proves that the angles at C and D must be congruent to each other and goes on to consider three hypotheses:

1. $\angle C$ and $\angle D$ are right angles.
2. $\angle C$ and $\angle D$ are obtuse angles.
3. $\angle C$ and $\angle D$ are acute angles.

He proves that if any one of these hypotheses is true for a single quadrilateral it is true for every quadrilateral; he also proves that depending upon whether hypothesis 1, 2, or 3 is assumed the sum of the angles of a triangle will be, respectively, equal to, greater than, or less than two right angles. He then goes on to show that on assuming the second hypothesis a contradiction is reached, and therefore the assumption must be discarded. To complete his argument, he attempts to eliminate the third hypothesis by assuming it is true.

To state all the theorems he derives under this assumption would needlessly repeat many of the theorems of the remaining sections of this book. Rather, let it be pointed out that instead of trusting to logic, Saccheri, predisposed to find a contradiction, finds one after a circuitous search located at a point at infinity—a point, needless to say, that causes a great deal of trouble.

Saccheri himself was not satisfied with the "contradiction" he reached and tried other methods, most of which had been tried many times over the centuries. If he had placed more faith in his reasoning and less faith in his faith, he would have been credited with the discovery of non-Euclidean geometry a hundred years before it was finally discovered. As it was, his work was soon forgotten and more or less remained so until it was resurrected late in the nineteenth century.

Johann H. Lambert (1728–1777)

Johann Lambert, a Swiss mathematician of the eighteenth century, was probably aware of Saccheri's work. His method of approach is quite similar except that, instead of a figure with two right angles, he starts out with a figure with three right angles. He, too, considers three hypotheses; all are about the nature of the fourth angle:

1. The fourth angle is a right angle.
2. The fourth angle is obtuse.
3. The fourth angle is acute.

On assuming the second hypothesis he easily obtains a contradiction. But once again in assuming the hypothesis of the acute angle a contradiction does not easily follow; however, he does reach several new conclusions. He proves, as did Saccheri, that the sum of the angles of any triangle is less than two right angles (the amount of the difference they call the *defect*); but, he goes a step further than Saccheri and proves that the defect of any polygon is *proportional to the area* of the polygon.

Furthermore, he comes up with still more astounding information, namely, that under this hypothesis there would be an *absolute unit of measure*. We shall discuss this concept later.

Once again, however, intuition takes precedence over logic and Lambert concludes that, since there can be no absolute unit of measure, this hypothesis must be false.

Gauss, Bolyai, Lobachevsky

Attacks on the Parallel Postulate continued and, indeed, grew more intense until the early 1820s. At that time a subtle change in outlook and objective became discernable among some of the mathematicians concerned with the problem.

In Germany, Carl Friederich Gauss (1777–1855) had been bringing his great gifts to bear upon the problem for some time. It was unfortunate for his contemporaries that he did not publish his findings. In letters to his friends, made public after his death, he expressly asked them not to reveal his findings while he lived. In these letters one discovers that he had gone a long way toward discovering and developing some of the properties of a new geometry that he called *non-Euclidean*. It is probable that he was the first to use this name.

Although it may never be known exactly what motivated him to keep his findings secret, it is likely that fear for his reputation may have been a factor. For, on the one hand, Gauss was recognized in his own lifetime as one of the greatest of mathematicians. On the other hand, he was aware that his discoveries would be shocking to layman and mathematician alike; indeed, they ran so counter to one's intuition that devulging them might have opened him to ridicule. At the same time, keeping his work secret meant that he never received the honor that might have been his due; the credit must go instead to the son of a friend of his and a young contemporary.

In Hungary, Johan Bolyai (1802–1860), and in Russia, Nicolai Ivanovich Lobachevsky (1793–1856) had each been working on the problem from 1820–1830. At the end of the decade they finally published their findings; ironically, it did not create any great stir and neither man achieved any fame for his accomplishment during his lifetime. Gauss read Bolyai's work within a year of publication and was pleased with it; he became aware of Lobachevsky's work somewhat later and was equally impressed. However, his praise was limited to correspondence with his friends and thus his immense prestige did nothing toward making either work known or accepted.

Instead of being pleased by Gauss's praise, Bolyai was disappointed and suspicious. He knew that his father and Gauss had corresponded for years; he had written his father of his discoveries in great detail years before they were finally published. Therefore, when Gauss praised his work but added that it was of the same kind that he himself had been working on, Bolyai felt that Gauss was attempting to gain credit for his own discovery.

According to the best historical detective work, each of the three men was ignorant of what the other was doing. It is not at all uncommon in the history of mathematics and the sciences for discoveries to be made simultaneously by different men, in scattered places, each ignorant of the others' work. It would seem that when an idea is ripe it will be forthcoming.

The work of Gauss, Bolyai, and Lobachevsky will be analyzed in detail as we continue.

B. Riemann (1826–1866)

The next great breakthrough occurred in 1854. Riemann, a student of Gauss and later one of the great mathematicians of his time, presented a paper in which he made a distinction between the infinitude of a line and its unboundedness. We have had occasion to refer to this before in regard to Euclid's Proposition 16, the exterior angle theorem. Let us recapitulate.

Suppose we consider a line drawn around a sphere, that is, a circle. It is not infinite in length; it has a definite circumference. Yet it is unbounded in the sense that we can continue around it without stop. Suppose now that we not only contradict the Parallel Postulate but also the assumption that lines are of infinite length. What happens then?

Because no one had considered this before the time of Riemann, no one had observed that in Saccheri's and Lambert's work the reason that the hypothesis of the obtuse angle leads to a contradiction is that they both assume that lines are of infinite length. If this assumption had not been made they would have reached no contradiction in pursuing the hypothesis of the obtuse angle.

Riemann suggested such a geometry, a geometry in which there are no parallel lines, lines may enclose a space, and the sum of the angles of a triangle is greater than two right angles. Unfortunately, the techniques needed to deal adequately with a discussion of Riemann's suggested geometry are beyond the limited scope of this text.

Felix Klein (1849–1925)

Work related to still another type of geometry developed in the nineteenth century, projective geometry, led Klein to classify the subject into three types: parabolic, elliptic, and hyperbolic geometry. They correspond respectively to the geometry of Euclid, Riemann, and Bolyai-Lobachevsky. The classifications are commonly used today.

In 1871 Klein pointed out that there are really two types of Riemann geometry. There is the spherical type in which two straight lines have two points in common and the elliptic type where two straight lines have but one point in common; because of the intersection properties of lines, these two geometries are often classified according to Klein's scheme as double-elliptic and single-elliptic respectively.

This discovery of Klein's helps us to solve the problem raised in Chapter 7 concerning the proof of the exterior angle theorem. It will be recalled that to prove that theorem we first had to prove Theorem 75, that through a point outside a given line there exists at least one parallel. This statement is consistent with both Euclidean and Bolyai-Lobachevskian geometry but it cannot hold in Riemann's. Euclid assumes that there is exactly one parallel; Bolyai and Lobachevsky assume that there is more than one; but Riemann assumes that there is none.

However, Theorem 75 was proved without assuming any parallel postulate; therefore, some axiom or axioms of our system must be eliminated if we are to get a geometry without parallels. (See Figure 7.8.)

An analysis of the proof of Theorem 75 indicates that the contradiction comes from a line intersecting another in two distinct points. For this to be a contradiction two facts must hold: there must be two distinct points of intersection and it must be impossible for two lines to intersect in more than one point. The second condition is Theorem 4, which follows from the Axiom that two points determine a unique line; the first condition is assured by D and G being on opposite sides of line AB, which is assured by the plane separation theorem, which in turn is assured by Pasch's Axiom. One begins to see that the geometry of Riemann is a strange one indeed. It turns out that in the spherical geometry two lines intersect in two points and that it is true that every line separates the plane; in single elliptic, on the other hand, two lines intersect in exactly one point but no line separates the plane.

The Age of Hilbert

In the late nineteenth century a new approach, the beginning of critical examinations into the foundations of geometry came into being. This period also brought an interesting epilogue to the history of attempts to prove the Parallel Postulate.

It was discovered that a considerable amount of Euclidean geometry could be developed without the Postulate of Archimedes; that is, without an assumption of continuity. Saccheri and Lambert and all the others had made generous use of continuity assumptions in their arguments. Now, with the foundations of geometry undergoing intense investigation, it was discovered that if the Postulate of Archimedes is rejected the Fifth does not follow from the assumption that the sum of the angles of a triangle is equal to two right angles. In other words, there can exist a non-Archimedean geometry in which the sum of the angles of every triangle is equal to two right angles but where the Fifth does not hold.

This is a fitting climax to the chain of events started by the Parallel Postulate. Now, in every way, Euclid has been vindicated. Not only has the parallel postulate been shown to be independent of the others (we shall discuss its independence in the last chapter) but his form of it has been proved superior to the other form; those statements that were once regarded as equivalent to the Fifth have proved to be so only when propped up by the Postulate of Archimedes.

Hopefully, the reader is fully prepared to investigate a new and unfamiliar geometry. We might, however, make a final clarification. Strictly speaking, any geometry that is not "Euclidean" may be called "non-Euclidean." Thus the finite geometries introduced in the beginning of the text are "non-Euclidean" geometries. Any geometry denying *any* statement of Euclidean geometry may be called "non-Euclidean." It is customary, however, to restrict this title to those geometries that deny the parallel postulate.

EXERCISES 9.1

1. Check the references listed at the end of Part III to find examples of fallacious proofs of the Fifth that involve direction, infinite areas, or some assumption equivalent to the Fifth.

2. What is wrong with the following: Given a line m and a perpendicular to m from a point A not on it. Let it intersect m at a point B. Through A there exists exactly one line perpendicular to line AB. This line is parallel (non-intersecting) to m. Therefore, we have proved that through a point not on a given line there exists at most one line parallel to the given line. (Suggestion: compare this with exercise 1, Exercises 7.2.)

9.2 The Geometry of Bolyai-Lobachevsky

To study the geometry of Bolyai and Lobachevsky, often called *hyperbolic* geometry, all we will need is a new axiom, namely, any denial of some form of the Euclidean parallel postulate. The particular form we choose makes a difference in the development of the system.

Since the time of Proclus most geometers have taken "Playfair's Axiom" as their choice for a parallel postulate. If this is the statement chosen, the contradiction takes the following form:

> Through a point not on a given line, more than one line can be drawn not intersecting the given line.

Indeed, this is the form used by Gauss, Bolyai, and Lobachevsky in beginning their studies of the new geometry.

Unfortunately, in order to begin in this manner, we are forced to introduce considerations of continuity. For it is known that there are two types of lines through a point not on a given line: those that intersect the given line and those that do not. It can be shown that there are an infinite number of each type. In the usual development it is then stated that the *first* of the nonintersecting lines are to be called the *parallels* and that there are two such first, or limiting, lines. But to assume or to prove that such lines exist one must implicitly or explicitly introduce continuity considerations.

To avoid this we shall adopt an axiom first suggested by Hilbert. We have modified it to make it much stronger than need be and thereby to get to the heart of the subject matter more quickly.

***Axiom 17* (*Hyperbolic Parallel Postulate, or HPP*).** If P is any point not on a given line m, then there exist exactly two rays, say $\overrightarrow{PR}$ and $\overrightarrow{PS}$, which:

(a) *are not opposite rays*

(b) *do not intersect* m

(c) *are such that any ray, say* $\overrightarrow{PQ}$, *intersects* m *iff* $\overrightarrow{PQ}$ *is between* $\overrightarrow{PR}$ *and* $\overrightarrow{PS}$.

***Definition 50*.** Each of the two rays whose existence is given in HPP is called a *parallel to* m *through* P.

Having introduced Axiom 17 it is now possible to prove some of the characteristic theorems of this new geometry. It should be kept in mind that every theorem proved in Chapters 5, 6, 7, and 8 will hold in the new geometry.

Axiom 17 tells us that any ray between the parallel rays to a line m must intersect m. A modification of this is presented as the first theorem in the new geometry.

***Theorem 108*.** With any point P (not on a line m) as endpoint, if a ray lies between a ray parallel to m, and a ray intersecting m, then it intersects m.

Restatement: *If* $\overrightarrow{PR}$ *and* $\overrightarrow{PS}$ *are the parallels through* P *to a line* m, *and if* B *is any point on* m, *then any ray* $\overrightarrow{PQ}$ *falling between* $\overrightarrow{PR}$ *and* $\overrightarrow{PB}$ *intersects* m.

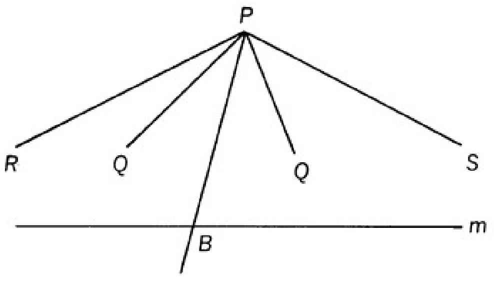

FIGURE 9.1

Proof: For if $\overrightarrow{PB}$ intersects m, then it follows from HPP that $\overrightarrow{PB}$ is between $\overrightarrow{PR}$ and $\overrightarrow{PS}$. If now $\overrightarrow{PQ}$ is a ray falling between $\overrightarrow{PR}$ and $\overrightarrow{PB}$, then it follows from Theorem 51a that $\overrightarrow{PQ}$ is between $\overrightarrow{PR}$ and $\overrightarrow{PS}$. Hence, from HPP it must intersect m.

Similarly, if ray $\overrightarrow{PQ}$ is between $\overrightarrow{PB}$ and $\overrightarrow{PS}$. ●

It will soon become evident that there are many nonintersecting lines that are not parallels. The next theorem says, in effect, that a parallel is the "first" of the nonintersecting lines.

Theorem 109. If $\overrightarrow{PQ}$ does not intersect a line m, but every ray between $\overrightarrow{PQ}$ and $\overrightarrow{PB}$, where B is a point on m, does intersect m, then $\overrightarrow{PQ}$ is parallel to line m.

Proof: Let m be a line, P a point not on it, $\overrightarrow{PQ}$ a ray that does not intersect m. By HPP there exist two rays $\overrightarrow{PR}$ and $\overrightarrow{PS}$ through P and parallel to m. Let B be any point on m such that it is false that B, P, and Q are collinear. Then Q falls on one side or the other of line PB. It follows from HPP that $\overrightarrow{PR}$ and $\overrightarrow{PS}$ must be on opposite sides of line PB; suppose Q falls on the R side of $\overrightarrow{PB}$.

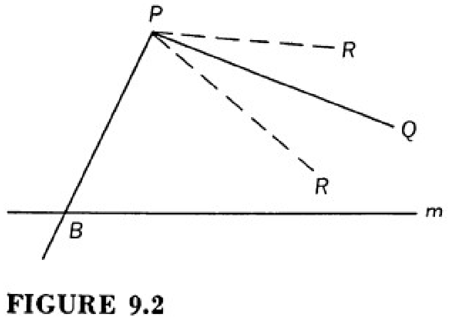

FIGURE 9.2

Now either $\overrightarrow{PR}$ is between $\overrightarrow{PB}$ and $\overrightarrow{PQ}$, $\overrightarrow{PQ}$ is between $\overrightarrow{PB}$ and $\overrightarrow{PR}$, or $\overrightarrow{PR} = \overrightarrow{PQ}$. (Why?)

By hypothesis, $\overrightarrow{PQ}$ does not intersect m; hence, it follows from Theorem 108 that it cannot lie between $\overrightarrow{PB}$ and $\overrightarrow{PR}$.

Also by hypothesis, every ray between $\overrightarrow{PQ}$ and $\overrightarrow{PB}$ intersects m; hence, by HPP, $\overrightarrow{PR}$ cannot lie between $\overrightarrow{PB}$ and $\overrightarrow{PQ}$.

It follows, therefore, that $\overrightarrow{PQ} = \overrightarrow{PR}$.

A similar argument holds if Q is on the S side of PB. ●

It follows as an immediate corollary of HPP that any perpendicular from a point P to a line m must lie between the parallels through P to line m. We can now show:

Theorem 110. If Q is the foot of the perpendicular from a given point P to a given line m, and $\overrightarrow{PR}$ and $\overrightarrow{PS}$ are the parallels through P to m, then $\angle RPQ \cong \angle SPQ$.

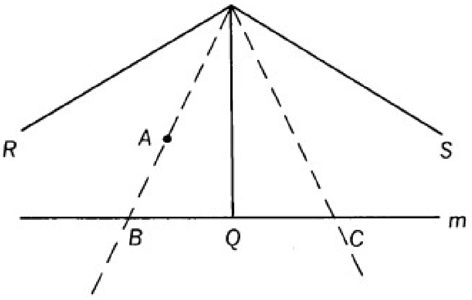

FIGURE 9.3

Proof: Suppose not. Then either $\angle SPQ < \angle RPQ$ or $\angle RPQ < \angle SPQ$. If $\angle SPQ < \angle RPQ$, then there exists a point A interior to $\angle RPQ$ such that $\angle APQ \cong \angle SPQ$ and, by Theorem 108, $\overrightarrow{PA}$ intersects m at a point B.

Now on m take C such that $B{*}Q{*}C$ and $B\text{–}Q \cong Q\text{–}C$ so that $\triangle BQP \cong \triangle CQP$ by SAS and therefore $\angle CPQ \cong \angle BPQ$. But $\angle APQ = \angle BPQ \cong \angle SPQ$. So by transitivity $\angle CPQ \cong \angle SPQ$, which implies that $\overrightarrow{PC}$ and $\overrightarrow{PS}$ are the same. (Why?)

But this is impossible because $\overrightarrow{PC}$ intersects m and $\overrightarrow{PS}$ does not. Hence, our assumption is false.

A similar argument eliminates $\angle RPQ < \angle SPQ$.

Hence, it follows that $\angle RPQ \cong \angle SPQ$. ●

The converse of Theorem 110 is also true.

Theorem 111. If $\overrightarrow{PR}$ and $\overrightarrow{PS}$ are the parallels through P to a given line m, then the bisector of $\angle RPS$ is perpendicular to line m.

Proof: Given that $\overrightarrow{PA}$ is the bisector of $\angle RPS$, it follows that $\overrightarrow{PA}$ must intersect m (why?) at some point Q, and that $\angle RPQ \cong \angle SPQ$. Suppose that $\overrightarrow{PQ}$ is not perpendicular to m.

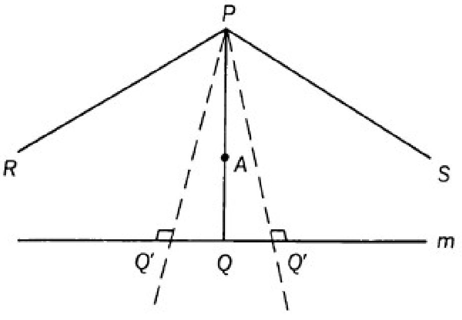

FIGURE 9.4

Then by Theorem 93 and Theorem 110 there exists a line PQ' through P and perpendicular to m, and such that $\angle RPQ' \cong \angle SPQ'$. Thus PQ' is also a bisector of $\angle RPS$, which contradicts Theorem 86.

It follows, therefore, that if $\overrightarrow{PA}$ is an angle bisector, it is also the perpendicular to m. ●

Although the diagrams have been drawn to indicate that the interior of the angle formed by parallel rays $\overrightarrow{PR}$ and $\overrightarrow{PS}$ contain m, this has not yet been established. Of course it would be quite embarrassing if false, for it would be almost painful to visualize condition (c) of Axiom 17 if the rays pointed upward. The next theorem assures us that the diagrams have not misled us. (See Figure 9.5.)

Theorem 112. If Q is the foot of the perpendicular from a point P to a given line m, and $\overrightarrow{PR}$ and $\overrightarrow{PS}$ are the parallels through P to m, then $\angle RPQ$ and $\angle SPQ$ are acute.

Proof: Suppose not. By Theorem 110 they must be congruent to each other. If they are both right angles, then $\overrightarrow{PR}$ and $\overrightarrow{PS}$ are opposite, contradicting HPP. If they are both obtuse, then $\overrightarrow{PE}$, the ray making a right angle with $\overrightarrow{PQ}$, would lie within $\angle SPQ$ or $\angle RPQ$ and hence by Theorem 108 would have to intersect m. By Theorem 78 this is impossible. The angles must, therefore, both be acute. ●

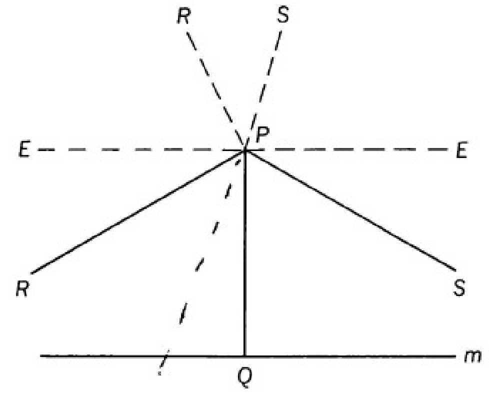

FIGURE 9.5

This theorem helps us to clarify a problem raised in Chapter 5. It was stated there that no angle analogue for Theorem 40 exists; that it cannot be proved that any line through an interior point of an angle, but not containing the vertex, cuts one of the sides. It should now be evident that to prove such a statement is, in effect, to prove the contradictory of Axiom 17. Therefore, it should be equally evident that to prove an analogue for Theorem 40 a Euclidean parallel postulate would be needed.

Using Theorem 112, it can now be proved that:

Theorem 113. If $\overrightarrow{PS}$ is a parallel through P to a line m, and N is a point of $\overrightarrow{PS}$ and X is any point such that $N*P*X$, then:

(a) It is false that $\overrightarrow{PX}$ is parallel to m
(b) It is false that $\overrightarrow{PX}$ intersects m
(c) Line PX ($= PS$) is nonintersecting with m.

Proof: Left as an exercise.

This theorem formally establishes some concepts that may have been intuitively evident; the theorem is not completely trivial, however. In this geometry that which is intuitively evident may be trivially true; on the other hand, it may be actually false. One must be careful of putting too much trust in one's intuition.

In keeping with this admonition, we shall carefully define some concepts whose meaning under other circumstances might very well have been left as part of the universal language.

Definition 51. Two noncollinear rays $\overrightarrow{PR}$ and $\overrightarrow{QS}$, where P and Q are distinct points, are said to be *in the same direction* iff they are on the same side of line PQ.

Definition 52. If $\overrightarrow{PS}$ is a parallel to m through P, and if $\overrightarrow{QX}$ is any ray on m, in the same direction as $\overrightarrow{PS}$, then $\overrightarrow{PS}$ is said to be *parallel to* $\overrightarrow{QX}$.

Let us carefully note the significance of Definition 52. Whereas HPP and Definition 50 tell us when a ray is parallel to a line, Definition 52 tells us when a ray is parallel to a ray. It tells us, for example, that while a ray may be parallel to a line, it is not parallel to *any* ray on that line. As illustrated in Figure 9.6, $\overrightarrow{PS}$ is parallel to m, and to $\overrightarrow{QX}$; but, $\overrightarrow{PS}$ is not parallel to $\overrightarrow{QY}$.

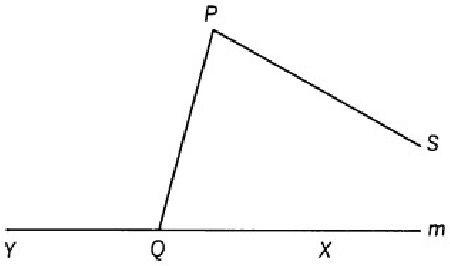

FIGURE 9.6

It is still not possible for us to speak of two *lines* being parallel to each other. In fact, because of the way in which parallels have been introduced, we have yet to answer the following question: if a ray is parallel through a point P to a line m, must it follow that at any other point on the line containing the ray there exists another ray on the line and parallel to m? The answer to this question is supplied by the next theorem.

Theorem 114. Let m be a line, P a point not on m, $\overrightarrow{PR}$ a parallel to m through P; if A is any point on the line containing $\overrightarrow{PR}$, that is, if *either* $P*A*R$, *or* $A*P*R$, then $\overrightarrow{AR}$ is parallel to m.

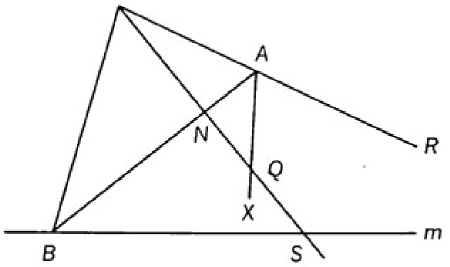

FIGURE 9.7

Proof:

Case 1. Let A be any point such that $P*A*R$; let B be any point on m; let X be any point interior to $\angle BAR$; and, let Q be any point on $\overrightarrow{AX}$ on the R side of m.

Now Q is interior to $\angle BAR$ (why?); it is also interior to $\angle BPR$. (Why?) It then follows, from Theorem 108 and Definition 18, that $\overrightarrow{PQ}$ intersects m in some point, say S. It is also the case that $\overrightarrow{PQ}$ intersects B–A in a point N. (Why?) So from Pasch's axiom applied to $\triangle BNS$ it follows that $\overrightarrow{AQ} = \overrightarrow{AX}$ intersects B–S. (Why?)

It was given that $\overrightarrow{AR}$ (as a subset of $\overrightarrow{PR}$) does not intersect line m. It has been shown that any ray $\overrightarrow{AX}$ interior to $\angle BAR$ intersects line m; therefore, by Theorem 109, $\overrightarrow{AR}$ is a parallel through P to line m.

(Because R is an arbitrary point, and because we wished to keep the statement of the theorem from becoming any more complicated, we have ignored the case $P*R*A$. But to include this case would lead to no difficulty because there always exists a point R' on $\overrightarrow{PR}$ such that $P*A*R'$ and the proof proceeds as in Case 1—except that the conclusion would then read that $\overrightarrow{AR'}$ is parallel to m.)

Case 2. Suppose now that A is a point such that $A*P*R$, B is any point on m, and X is any interior point of $\angle BAR$. Then there exists a point Q on $\overrightarrow{AX}$ such that Q is on the A side of m, and the A side of line BP. (Why?)

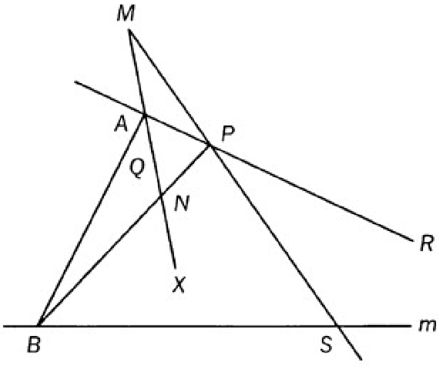

FIGURE 9.8

Let M be a point such that $Q*A*M$. Then $\overrightarrow{MP}$ intersects line m in some point, say S. (Why?)

In $\triangle BAP$, $\overrightarrow{AQ}$ intersects B–P in some point N; in $\triangle BPS$, $\overrightarrow{AQ} = \overrightarrow{AX}$ intersects B–S. (Why?)

From Theorem 113 it follows that $\overrightarrow{AR}$ (as a subset of line AR) does not intersect line m. It has been shown that any ray $\overrightarrow{AX}$ interior to $\angle BAR$ must intersect line m; therefore, by Theorem 109, $\overrightarrow{AR}$ is a parallel through A to line m. ●

Once Theorems 113 and 114 have been proved it is possible to offer the following definition with the assurance that it is meaningful.

Definition 53. Given $\overrightarrow{PS}$ is a parallel to m and given X, Y are points on line PS, then $\overrightarrow{XY}$ is said to be *parallel to m in the same sense* as $\overrightarrow{PS}$ iff $\overrightarrow{XY}$ is not opposite $\overrightarrow{XS}$.

Language Rule 17. *If $\overrightarrow{PS}$ is parallel to m, then it is possible to speak of* LINE *PS being* PARALLEL TO *m* IN THE SAME SENSE; *if this language is used, however, one must then distinguish between line sense PS and line sense SP.*

We conclude this section by proving two theorems that show how parallels of this geometry are quite like those of Euclidean geometry and by proving one theorem that shows how different they are.

Although Definition 52 tells us under what circumstances $\overrightarrow{PS}$ can be said to be parallel to $\overrightarrow{QX}$, it does not guarantee that $\overrightarrow{QX}$ will be parallel to $\overrightarrow{PS}$. Theorem 115 fills this gap.

Theorem 115. Two rays are always mutually parallel.

Restatement: *If $\overrightarrow{AR}$ is a parallel to $\overrightarrow{BS}$, it is to be shown that $\overrightarrow{BS}$ is a parallel to $\overrightarrow{AR}$.*

Proof: From A drop a perpendicular to $\overrightarrow{BS}$ intersecting at a point C. We know that $\overrightarrow{CS}$ would have to be nonintersecting with $\overrightarrow{AR}$; to show that it is parallel we shall use Theorem 109. Thus, it is to be shown that any ray interior to $\angle ACS$ intersects $\overrightarrow{AR}$.

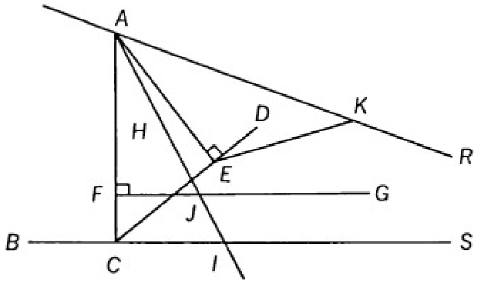

FIGURE 9.9

Let $\overrightarrow{CD}$ be a ray interior to $\angle ACS$, with D on the B side of $\overrightarrow{AR}$. Now from A let $A-E$ be perpendicular to line CD; E must fall on $\overrightarrow{CD}$ because $\angle DCS$, $\angle ACD$ are acute angles and, therefore, E cannot coincide with C or be on the opposite side of AC without contradicting the exterior angle theorem. Hence, E lies interior to $\angle ACS$.

Therefore, $\angle ACE$ is an acute angle, and $\angle AEC$ is a right angle of $\triangle AEC$, so by Theorem 82 $A-E < A-C$.

Now on $A-C$ there exists a point F such that $A-F \cong A-E$; let FG be perpendicular to $A-C$ and on the same side of $A-C$ as R and S.

E also lies interior to $\angle CAR$ (or else, $\overrightarrow{CE}$ meets $\overrightarrow{AR}$), so $\angle EAR < \angle FAR$. Let $\angle FAH \cong \angle EAR$. Then by Theorem 108 $\overrightarrow{AH}$ must meet $\overrightarrow{BS}$ in some point I. So in $\triangle ACI$, line FG must meet $A-I$ in some point J.

On $\overrightarrow{AR}$ let K be a point such that $A-K \cong A-J$. Then $\triangle AFJ \cong \triangle AEK$ by SAS. So corresponding angles $\angle AFJ$, $\angle AEK$ are congruent. But $\angle AFJ$ is a right angle; therefore, $\angle AEK$ is a right angle. By construction, $\angle AED$ is a right angle, therefore, $\overrightarrow{ED} = \overrightarrow{EK}$ and $\overrightarrow{CE}$ intersects $\overrightarrow{AR}$ at K.

It follows from Theorem 109 that $\overrightarrow{CS}$ is parallel to $\overrightarrow{AR}$, and hence by Theorem 114 that $\overrightarrow{BS}$ is parallel to $\overrightarrow{AR}$. ●

This theorem assures us that the parallel property for rays is a symmetric property. What about transitivity? Before one jumps to a conclusion on this question a look at HPP might be of value. Observe that while $\overrightarrow{PR}$ and $\overrightarrow{PS}$ are each parallel to m they are not parallel to each other. Thus if there is to be a transitivity property it must be restricted as in Theorem 116.

Theorem 116. If two rays are each parallel (in the same direction) to a third, then they are parallel to one another.

Proof: There are two cases to be considered: the case in which the two rays are on opposite sides of the third and the case in which they are on the same side of the third.

Case 1. Let $\overrightarrow{AR}$, $\overrightarrow{CT}$ both be parallel to $\overrightarrow{BS}$ on opposite sides of $\overrightarrow{BS}$. Then $A-C$ must meet $\overrightarrow{BS}$ in a point D. (See Figure 9.10.)

Let $\overrightarrow{AE}$ be any ray through A between $\overrightarrow{AC}$ and $\overrightarrow{AR}$. Then by Theorem 108 this line will meet $\overrightarrow{BS}$ in a point, say F. Join $C-F$. Since $\overrightarrow{CT}$ is parallel to $\overrightarrow{BS}$, then by Theorem 115, $\overrightarrow{BS}$ is parallel to $\overrightarrow{CT}$, and by Theorem 114, $\overrightarrow{FS}$ is parallel to $\overrightarrow{CT}$. $\overrightarrow{FE}$ is interior to $\angle CFS$ (why?), so $\overrightarrow{FE} = \overrightarrow{AE}$ will meet $\overrightarrow{CT}$.

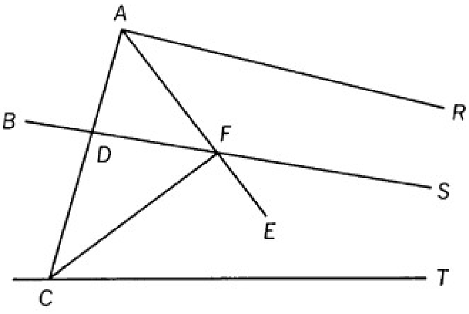

FIGURE 9.10

Since $\overrightarrow{AR}$ does not intersect $\overrightarrow{CT}$ (why?), but any line through A interior to $\angle CAR$ does, it follows from Theorem 109 that $\overrightarrow{AR}$ and $\overrightarrow{CT}$ are parallel.

Case 2. Suppose now that $\overrightarrow{AR}$ and $\overrightarrow{CT}$ are on the same side of $\overrightarrow{BS}$ and each is parallel to it. Then $\overrightarrow{AR}$ and $\overrightarrow{CT}$ cannot intersect. For if they did intersect, say in a point X, then through X there would exist two rays parallel (in the same direction) to a third. This is impossible. (Why?) Thus, they do not intersect, and either $\overrightarrow{AR}$ and $\overrightarrow{BS}$ are on opposite sides of $\overrightarrow{CT}$ or $\overrightarrow{CT}$ and $\overrightarrow{BS}$ are on opposite sides of $\overrightarrow{AR}$.

The proof is similar in either case; let us suppose the former, that is, that $\overrightarrow{AR}$ and $\overrightarrow{BS}$ are on opposite sides of $\overrightarrow{CT}$.

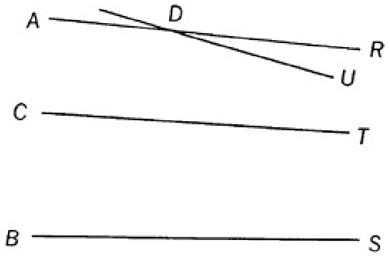

FIGURE 9.11

Suppose $\overrightarrow{AR}$ is not parallel to $\overrightarrow{CT}$. Then through any point D of $\overrightarrow{AR}$ there exists a ray $\overrightarrow{DU}$ parallel to $\overrightarrow{CT}$. It follows from Case 1 that $\overrightarrow{DU}$ is parallel to $\overrightarrow{BS}$. We already have that $\overrightarrow{AR}$ is parallel to $\overrightarrow{BS}$, so from Theorem 114 it follows that $\overrightarrow{DR}$ is parallel to $\overrightarrow{BS}$.

But from HPP, in the same direction, only one parallel to line BS can exist through a point D not on it. Therefore, $\overrightarrow{DU}$ must coincide with $\overrightarrow{DR}$ and thus $\overrightarrow{AR}$ is parallel to $\overrightarrow{CT}$. ●

We have now shown that if certain restrictions are made the parallels in this geometry have some of the properties of parallels in Euclidean geometry. It has also been shown that in this geometry there exists a distinction between "nonintersecting" lines and "parallel" lines; for, while all parallels are nonintersecting, it is not the case that all nonintersecting lines are parallels. Theorem 109, in effect, showed that parallels are the first of the nonintersecting lines. The next theorem (together with Theorem 77) establishes a more basic difference in their characteristics.

Theorem 117. Corresponding angles formed by two parallels and any transversal are not congruent.

Restatement: *Let $\overrightarrow{XR}$ and $\overrightarrow{YS}$ be parallel rays and line AB a transversal with A on $\overrightarrow{XR}$ and B on $\overrightarrow{YS}$; let C be a point such that $B*A*C$. It is to be proved that $\angle CAR$ is not congruent to $\angle CBS$.*

Proof: By Theorem 114 and Definition 52, $\overrightarrow{AR}$ and $\overrightarrow{BS}$ are parallel rays. Suppose now that $\angle CAR \cong \angle CBS$.

They cannot be right angles, for then $\angle BAR \cong \angle ABS$, contradicting Theorem 112.

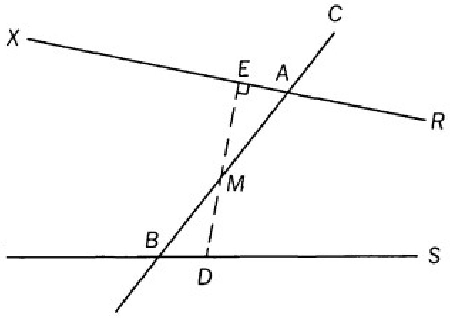

FIGURE 9.12

Let M be the midpoint of A–B and let the perpendicular from M to line AR intersect at a point E, which by the preceding statement is distinct from A. Whichever side of line AB point E falls on, take D on the opposite side of line AB such that B–$D \cong A$–E. It can then be shown that $\triangle MEA \cong \triangle MDB$ by SAS, and thus concluded that $\angle EMA \cong \angle DMB$.

Now since $\angle DMB$, $\angle DMC$ form a linear pair and $\angle EMA \cong \angle DMB$, then $\angle EMA$, and $\angle DMC$ are supplementary. (Why?) So by Theorem 62, Corollary 3, $\angle DMC$ and $\angle EMA$ form a linear pair; and, by Definitions 13 and 25, EMD is a (straight) line.

From the congruent triangles it follows that $\angle AEM \cong \angle MDB$; so, from Theorem 90 it follows that $\angle MDB$ is a right angle and by Definition 38 that $\angle MDS$ is a right angle.

It has now been shown that there exists a transversal ED of parallels $\overrightarrow{ER}$ and $\overrightarrow{DS}$ (using Theorem 114), such that $\angle RED$ and $\angle SDE$ are right angles. This contradicts Theorem 112.

Thus the assumption must be false and $\angle CAR$ and $\angle CBS$ are not congruent. ●

Corollary: *Alternate interior angles formed by two parallel lines and any transversal are not congruent.*

EXERCISES 9.2

1. Complete the proof of Theorems 110 and 111.
2. Prove Theorem 113.
3. Complete the proof of Theorem 114.
4. Complete the proof of Theorem 116.

9.3 A New Kind of Triangle

When two nonintersecting lines are met by a transversal the resulting figure is given no special name. When two parallel lines are met by a transversal, however, the resulting figure has some interesting properties and is sometimes called a *limit triangle* or an *asymptotic triangle.* Each of these names is descriptive in its own way but is also rather suggestive. So we shall merely call it a T-V-T (two-vertices-triangle). The following definition makes this more precise.

Definition 54. Given: any two parallel rays $\overrightarrow{XR}$ and $\overrightarrow{YS}$ met by a transversal m, at points A and B with $X{*}A{*}R$ and $Y{*}B{*}S$:

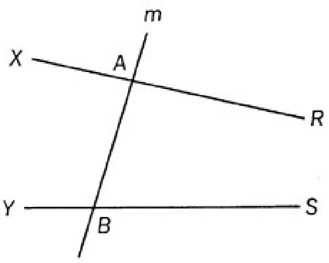

FIGURE 9.13

(a) The union of $\overrightarrow{AR}$, $\overrightarrow{BS}$, A, B and $A\text{–}B$ is called a *T-V-T*.

(b) The segment $A\text{–}B$ is called the *side* of the T-V-T.

(c) The angles $\angle BAR$ and $\angle ABS$ are called the *angles* of the T-V-T; also the *interior angles*.

(d) A, B are called the *vertices*.

(e) The angles $\angle XAB$, $\angle YBA$ and their respective vertical angles are called *exterior* angles of the T-V-T.

(f) An interior angle and an exterior angle of a T-V-T that are not adjacent are called *opposite interior* and *opposite exterior* angles relative to one another.

(g) The *interior* of a T-V-T is the intersection of:

- (i) The R side of line AB
- (ii) The B side of line AR
- (iii) The A side of line BS

(h) The *exterior* of a T-V-T is the set of all points which are neither on the T-V-T nor in its interior.

Notation Rule 19. *A* T-V-T *with rays* $\overrightarrow{AR}$ *and* $\overrightarrow{BS}$ *joined by segment* $A\text{–}B$ *will be denoted by:*

$$RABS$$

The figure has some of the properties of any ordinary triangle as shown by the following theorems.

Theorem 118. If a line passes through a point P interior to a T-V-T $RABS$, then:

(a) a line through P and either vertex intersects the other ray;

(b) a line through P and parallel to either ray intersects the side.

Proof:

Case a. Suppose that P lies interior to $RABS$. Then $\overrightarrow{AP}$ must intersect $\overrightarrow{BS}$ in some point C and, similarly, $\overrightarrow{BP}$ must intersect $\overrightarrow{AR}$; in each case this follows from Theorem 108.

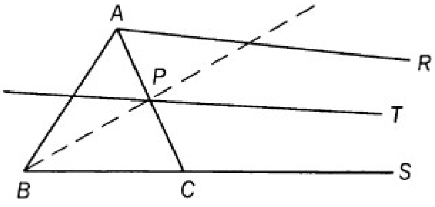

FIGURE 9.14

Case b. Suppose P lies interior to $RABS$ and $\overrightarrow{PT}$ is a ray parallel to either $\overrightarrow{AR}$ or $\overrightarrow{BS}$. Since $\overrightarrow{PT}$ intersects $A\text{–}C$ at P and is parallel to $\overrightarrow{BS}$, then by Pasch's axiom it must intersect $A\text{–}B$. ●

Theorem 119. If a line not through a vertex of a T-V-T:

(a) intersects either ray, then it intersects the other ray, or the side;

(b) intersects the side, and is not parallel to either ray, then it intersects one of the two rays.

Proof:

Case a. If line m intersects a ray, say $\overrightarrow{AR}$ of $RABS$ at C, and does not go through a vertex, then m is not the same line as line BC. Therefore, there exists a point X which is interior to $RABS$ and either on the R side of BC or on the A side of BC. (Why does such a point exist?)

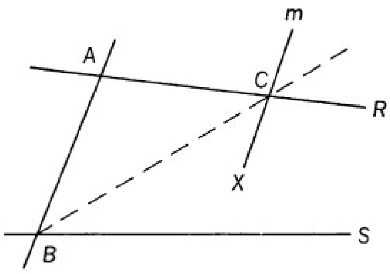

FIGURE 9.15

If it is on the R side, then it lies in $\angle BCR$ and so, by Theorems 108 and 114, it must intersect $\overrightarrow{BS}$. If it is on the A side of line BC, then in $\triangle ACB$, m intersects $A\text{–}B$, by Theorem 39.

Case b. If m intersects $A\text{–}B$ at some point, say C, and is not parallel to either ray, then let $\overrightarrow{CT}$ be such a parallel. Then $RACT$ and $TCBS$ are T-V-T triangles. Line m has a point X either in $\angle ACT$ or $\angle BCT$ (but not

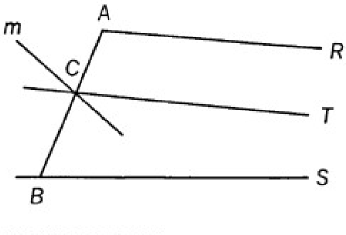

FIGURE 9.16

Case b. Suppose P lies interior to $RABS$ and $\overrightarrow{PT}$ is a ray parallel to either $\overrightarrow{AR}$ or $\overrightarrow{BS}$. Since $\overrightarrow{PT}$ intersects $A–C$ at P and is parallel to $\overrightarrow{BS}$, then by Pasch's axiom it must intersect $A–B$. ●

Theorem 119. If a line not through a vertex of a T-V-T:

(a) intersects either ray, then it intersects the other ray, or the side;

(b) intersects the side, and is not parallel to either ray, then it intersects one of the two rays.

Proof:

Case a. If line m intersects a ray, say $\overrightarrow{AR}$ of $RABS$ at C, and does not go through a vertex, then m is not the same line as line BC. Therefore, there exists a point X which is interior to $RABS$ and either on the R side of BC or on the A side of BC. (Why does such a point exist?)

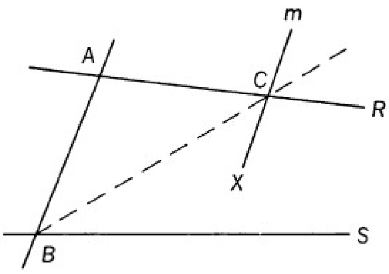

FIGURE 9.15

If it is on the R side, then it lies in $\angle BCR$ and so, by Theorems 108 and 114, it must intersect $\overrightarrow{BS}$. If it is on the A side of line BC, then in $\triangle ACB$, m intersects $A–B$, by Theorem 39.

Case b. If m intersects $A–B$ at some point, say C, and is not parallel to either ray, then let $\overrightarrow{CT}$ be such a parallel. Then $RACT$ and $TCBS$ are T-V-T triangles. Line m has a point X either in $\angle ACT$ or $\angle BCT$ (but not

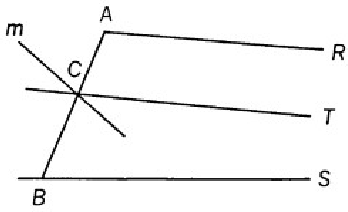

FIGURE 9.16

Theorem 121. If in two T-V-T triangles, an angle of one is congruent to an angle of the other, and the sides are congruent, then the remaining angles are congruent.

Restatement: *Given two* T-V-T *triangles* $RABS$ *and* $R'A'B'S'$, *in which* $\angle B \cong \angle B'$, *and* $A\text{–}B \cong A'\text{–}B'$, *prove that* $\angle A \cong \angle A'$.

Proof: Suppose that $\angle A' < \angle A$. Then there exists a point C such that $\angle BAC \cong \angle B'A'R'$, and C is interior to $\angle BAR$; hence, by Theorem 108, $\overrightarrow{AC}$ intersects $\overrightarrow{BS}$ at some point D.

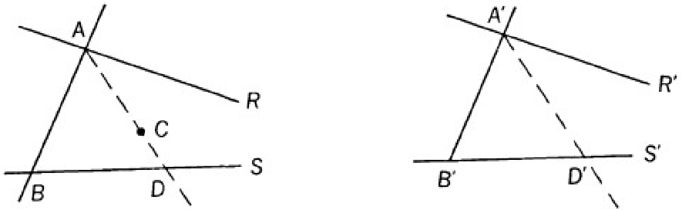

FIGURE 9.18

On $\overrightarrow{B'S'}$ there exists a point D' such that $B\text{–}D \cong B'\text{–}D'$. Then by SAS, $\triangle ABD \cong A'B'D'$, and $\angle BAD \cong \angle B'A'D'$. But $\angle BAD \cong \angle B'A'R'$; hence, by transitivity, $\angle B'A'D' \cong \angle B'A'R'$, which contradicts Axiom 14 (why?).

Similarly, if $\angle A < \angle A'$.

Therefore, by the Trichotomy theorem it follows that $\angle A \cong \angle A'$. ●

The next theorem is astonishingly different from anything in Euclidean geometry.

Theorem 122. If in two T-V-T triangles the angles of one are congruent to the angles of the other, then the sides are congruent.

Proof: Given that $\angle A \cong \angle A'$, $\angle B \cong \angle B'$, it is to be shown that $A\text{–}B \cong A'\text{–}B'$ in the two T-V-T triangles $RABS$ and $R'A'B'S'$.

Suppose $A'\text{–}B' < A\text{–}B$. Then there exists a point C on $A\text{–}B$ such that $B\text{–}C \cong B'\text{–}A'$, and through C there exists a parallel, say $\overrightarrow{CT}$, to $\overrightarrow{AR}$ and hence, by Theorem 116, to $\overrightarrow{BS}$.

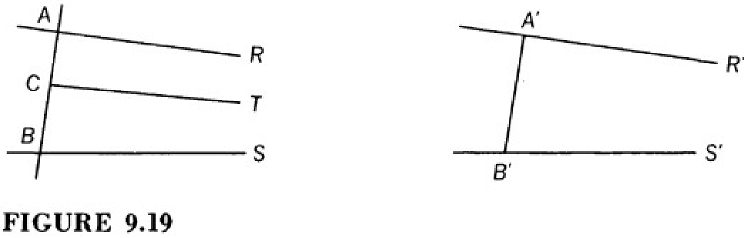

FIGURE 9.19

By Theorem 121 $\angle BCT \cong \angle A'$; but, since $\angle A' \cong \angle A$, it follows that $\angle A \cong \angle BCT$, which contradicts Theorem 117 (as well as Theorem 120). Hence, our assumption is false.

Similarly, if $A\text{–}B < A'\text{–}B'$.

So, by the Trichotomy for Segments theorem, $A\text{–}B \cong A'\text{–}B'$. ●

EXERCISES 9.3

1. Prove that in a T-V-T $RABS$, the bisector of each of the two angles intersects in a point interior to $RABS$.

2. A T-V-T is called *isosceles* if its two *angles* are congruent. Prove that if the sides of two isosceles *T-V-T*s are congruent, then the angles of each are congruent to the angles of the other.

3. Prove that the perpendicular bisector of the side $A\text{–}B$ of an isosceles T-V-T $RABS$ is parallel to the rays $\overrightarrow{AR}$ and $\overrightarrow{BS}$.

4. Prove that if $\overrightarrow{CT}$ is the perpendicular bisector of $A\text{–}B$ in isosceles T-V-T $RABS$, then the perpendiculars from any point on $\overrightarrow{CT}$ to $\overrightarrow{AR}$ and $\overrightarrow{BS}$ are congruent.

5. Prove that if the perpendicular bisector $\overrightarrow{CT}$ of $A\text{–}B$ in $RABS$ is parallel to $\overrightarrow{AR}$ and $\overrightarrow{BS}$, then $RABS$ is isosceles.

10 New Shapes

Even when an author treats his subject as comprehensively as possible, he must use a certain amount of selectivity to keep the book from becoming unwieldy. Since it is not our aim to be comprehensive, a great deal of material must be left out or slighted. One should not assume that the deleted material is less important than that which is included.

If the subject matter is unadaptable or extraneous to the development of the text, there is no problem. However, many of the topics that might have been discussed in this chapter fall into the category of borderline cases both as to adaptability and relevance. In such a case the choice of materials to be included or deleted is arbitrary. It would have been possible, for example, to discuss the concept of *corresponding points,* which have as a locus the curve called a *horocycle* or the *equidistant* curve. We also might have examined *equivalent polygons* and their relevance to the *measurement of area.*

We have chosen to consider topics that are more obviously relevant to the development of the rest of the text and that easily generate interesting and instructive exercises. But the reader is encouraged to pursue additional topics on his own; many stimulating ones will be found in the references listed at the end of Part III.

10.1 Absolute Geometry

In Chapter 2 of this text we presented and discussed three axiom systems: 1, 2, and 3. It will be remembered that Axiom Sets 1 and 2 differed in only one axiom. In Axiom Set 1 there was a Euclidean parallel axiom; in Axiom Set 2 there was an axiom which said that no nonintersecting lines exist. It should be recognized that this situation is comparable to the relationship between Euclidean and hyperbolic geometry. For here, too, both systems have the same set of axioms except for one; but in this case the denial of the Euclidean parallel axiom takes the form of asserting the existence of more than one parallel rather than saying that there are none. The comparison carries further.

Axiom Set 3 was created by taking the set of all axioms common to the other two. Thus it was evident that all of the theorems derived from this set must of necessity hold in both of the other systems. In fact, Axiom System 3 was a *part* of each of the other systems; the same theorems would have resulted if we had worked in either of the other systems and merely refrained from ever using Axiom 5 in a proof. A completely analogous situation holds in the relationship between Euclidean geometry and hyperbolic geometry.

The founders of hyperbolic geometry were aware of this common core of subject matter. Bolyai, in particular, was very much interested in the theorems common to the new geometry and Euclidean geometry, and gave them a name. He called this system of axioms and theorems *absolute* geometry.

The reader should now be able to appreciate why, in developing the material of Chapters 5, 6, 7, and 8, no use was made of a parallel postulate. It was excluded to make the material available in Chapters 9 and 10.

As stated in Section 8.5, there was no need to stop at Theorem 107. There is literally no end to the number of theorems that could have been proved. Those theorems that would be needed were proved and those for which there was no immediate need were not proved. On the same basis we must now introduce several more theorems of absolute geometry.

Theorem 123. A point is interior to a convex quadrilateral iff it lies between: two points on opposite sides; two points on adjacent sides; a vertex and a point on a side not having that vertex as endpoint; opposite vertices.

Proof: Left as an exercise.

Theorem 124. The segment between points on opposite sides of a convex quadrilateral must intersect the segment between points on the other two opposite sides.

Proof: Left as an exercise.

Theorem 125. In a convex quadrilateral the (rays containing the) diagonals lie interior to the angles with which they have a common vertex.

Proof: Left as an exercise.

Theorem 126. (a) The line joining points on opposite sides of a convex quadrilateral "divides" it into two convex quadrilaterals.

(b) A diagonal of a convex quadrilateral "divides" it into two triangles.

Proof: Left as an exercise.

Theorem 127. If $ABCD$ is any convex quadrilateral with right angles at $\angle A$ and $\angle B$, and E is a point such that $A{*}E{*}B$, then any line perpendicular to line AB at E must intersect segment $C–D$.

Proof: Left as an exercise.

Theorem 128. If $ABCD$ is any convex quadrilateral with right angles at $\angle A$ and $\angle B$, and E is any point such that $C{*}E{*}D$, then the line which passes through E and which is perpendicular to line AB intersects segment $A–B$.

Proof: Left as an exercise.

EXERCISES 10.1

*5. Prove Theorem 126b.

6. Prove Theorem 127.
7. Prove Theorem 128.

10.2 New Quadrilaterals

In this section we shall introduce two figures briefly mentioned in the section on history. Both Saccheri and Lambert introduced quadrilaterals from which they attempted to prove the Parallel Postulate. It will be remembered that before claiming a tenuous victory, each had derived a great many theorems from his hypothesis of the acute angle.

Since we have already introduced the HPP we shall be approaching the material from a different perspective. This in no way detracts from the fascination of these figures. The Saccheri quadrilateral, in particular, we find to be one of the most interesting figures in geometry. We trust that before long the reader will agree.

Definition 55. A convex quadrilateral $ABCD$ in which $\angle A$ and $\angle B$ are right angles and $A\text{–}D \cong B\text{–}C$ is called a *Saccheri Quadrilateral.* $A\text{–}B$ is called the *base.* $D\text{–}C$ is called the *summit.* Angles $\angle D$ and $\angle C$ are called the *summit angles.*

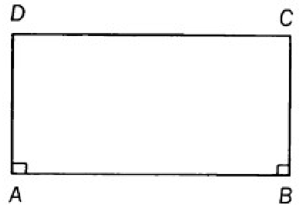

FIGURE 10.1

Notation Rule 20. *The quadrilateral defined in Definition 55 will be denoted by:*

S.Q. $ABCD$

where the first two letters of the quadrilateral named always represent the right angles.

According to the definition, any quadrilateral with two right angles and congruent *sides* qualifies as a Saccheri Quadrilateral. Therefore, as far as the definition is concerned, it is possible to refer to a square or a rectangle as a Saccheri Quadrilateral. This is true if we remain in absolute geometry, as we do in the next four theorems.

Theorem 129. If a line passes through the midpoints of the base and summit of a S.Q., then it is perpendicular to both of them.

Proof: Given a S.Q. $ABCD$ with points E, F, such that $A*E*B$, $D*F*C$, and $A\text{–}E \cong E\text{–}B$, $D\text{–}F \cong F\text{–}C$, it is to be shown that $EF \perp AB$ and $EF \perp DC$.

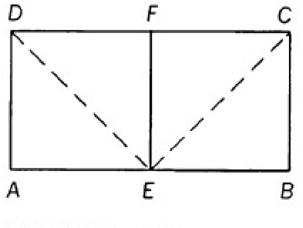

FIGURE 10.2

It follows immediately from the definition of S.Q. and from what is given that $\triangle DAE \cong \triangle CBE$. Hence, $\angle AED \cong \angle BEC$ and $D\text{–}E \cong C\text{–}E$.

$\triangle DFE \cong \triangle CFE$ by *SSS*. Hence, $\angle DFE \cong \angle CFE$ and, therefore, by definition, are right angles.

It must be the case that $\overrightarrow{ED}$ is between $\overrightarrow{EA}$ and $\overrightarrow{EF}$, and that $\overrightarrow{EC}$ is between $\overrightarrow{EB}$ and $\overrightarrow{EF}$. (Why?)

By corresponding parts of congruent triangles, $\angle DEF \cong \angle CEF$, and since we have already established that $\angle AED \cong \angle BEC$, it follows from Theorem 64 on addition of adjacent angles, that $\angle AEF \cong \angle BEF$. Since by definition they form a linear pair, they must be right angles.

By definition it now follows that $EF \perp AB$ and $EF \perp DC$. ●

Corollary: *The lines containing the base and summit of a S.Q. are nonintersecting and nonparallel lines.*
Proof: Follows from Theorems 129, 78, and 117.

Theorem 130. If a line is the perpendicular bisector of the base of a S. Q. it is also the perpendicular bisector of the summit.

Proof: Given a S.Q. *ABCD* with a point *E* such that $A*E*B$ and $A\text{–}E \cong E\text{–}B$, it is to be shown that there exists a point *F* such that $D*F*C$, such that the perpendicular bisector of $A\text{–}B$ passes through *F* and such that $EF \perp DC$ and $D\text{–}F \cong F\text{–}C$.

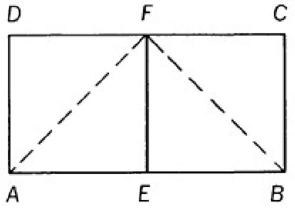

FIGURE 10.3

It follows from Theorem 127 that there exists a point *F* such that $D*F*C$ and such that the perpendicular bisector of $A\text{–}B$ passes through *F*.

$\triangle AEF \cong \triangle BEF$ by *SAS*. Hence $A\text{–}F \cong B\text{–}F$, $\angle EAF \cong \angle EBF$.

It must be the case that $\overrightarrow{AF}$ is between $\overrightarrow{AD}$ and $\overrightarrow{AE}$ and that $\overrightarrow{BF}$ is between $\overrightarrow{BE}$ and $\overrightarrow{BC}$. (Why?)

By definition, $\angle A$, $\angle B$ are right angles and thus $\angle A \cong \angle B$. It then follows (from what has just been established) from Theorem 65 on the subtraction of adjacent angles, that $\angle DAF \cong \angle CBF$. Since $D\text{–}A \cong C\text{–}B$, it follows by *SAS* that $\triangle DAF \cong \triangle CBF$ and thus that $D\text{–}F \cong F\text{–}C$.

But now, by Theorem 64 (Addition), it follows that $\angle DFE \cong \angle CFE$ and, since they form a linear pair, that they are right angles. So by definition $EF \perp DC$.

Therefore, by definition, EF is the perpendicular bisector of D–C. ●

Theorem 131. The perpendicular bisector of the summit of a S.Q. is also the perpendicular bisector of the base.

Proof: Left as an exercise. (Hint: prove by contradiction.)

Theorem 132. The summit angles of a S.Q. are congruent.

Proof: Left as an exercise.

If we ignore the Corollary to Theorem 129, which requires a hyperbolic theorem and definition in its proof, it will be seen that the proofs of these theorems use only the theorems from absolute geometry; each of them is true for squares and rectangles.

It is not often, however, that squares and rectangles are called Saccheri Quadrilaterals. This is because of the characteristic properties the latter have in hyperbolic geometry. This is brought out sharply in the next theorem.

In studying the proof of this fundamental theorem it should not pass unnoticed how much of the preceding development of this text is required for its solution.

Theorem 133. The summit angles of a S.Q. are acute.

Proof: In S.Q. $ABCD$, let E be a point such that $D*C*E$, and let F be a point such that $A*B*F$.

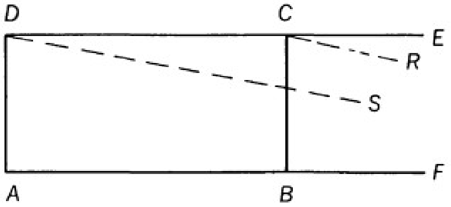

FIGURE 10.4

Let $\overrightarrow{DS}$ be parallel to $\overrightarrow{AB}$ and let $\overrightarrow{CR}$ be parallel to $\overrightarrow{BF}$, then $\overrightarrow{DS}$ and $\overrightarrow{CR}$ are both parallel to $\overrightarrow{AB}$ and to each other. (Why?)

By the Corollary to Theorem 129, the base and summit of a S.Q. are nonparallel and nonintersecting; hence, it follows that $\overrightarrow{DS}$ is between $\overrightarrow{DA}$ and $\overrightarrow{DC}$ and that $\overrightarrow{CR}$ is between $\overrightarrow{CB}$ and $\overrightarrow{CE}$. (Why?)

Now from Theorem 121 it follows that in the two T-V-T triangles *SDAF* and *RCBF*, $\angle SDA \cong \angle RCB$. Furthermore, from Theorem 120 it follows that in T-V-T *RCDS*, $\angle CDS < \angle ECR$. Hence, using Theorem 104 and Definitions 46 through 49, it follows that $\angle CDA < \angle ECB$.

According to Theorem 132 $\angle CDA \cong \angle DCB$; therefore, from Theorem 67 (Presubstitution) it follows that $\angle DCB < \angle ECB$.

Because $\angle DCB$, $\angle ECB$ form a linear pair they are supplementary. Because $\angle DCB < \angle ECB$ they are not right angles. Therefore, using Definition 38, Theorems 89b, 89a, and 88, it follows that $\angle DCB$ is acute.

Thus, it follows that $\angle CDA$ is acute. (Why?) ●

This theorem has a traumatic effect on one's intuition. It is one thing to agree that there can exist two parallels to a given line through a given point; one can almost do this abstractly. When this is accepted, one still has to cope with the idea that the parallel rays "point downward"; if they are to be nonintersecting, intuition would have them "pointing upward." This is strange, but one can adjust to it. Now, however, something new enters the discussion.

We have never examined the properties of the lines in this system. We know that "line" is an undefined term; by the axioms assumed, especially the *betweenness* axioms, it is plausible to regard them as "straight" lines. This has been done in all of the figures presented up to this point, and if we had not entered the realm of hyperbolic geometry no question would have been raised. But what now?

Observe that the sides of a Saccheri Quadrilateral are congruent; it has now been shown that the summit angles are acute. How then does one draw the summit? Notice (in Figure 10.5) that if one draws the summit straight, the angles do not look acute; if one draws the angles acute, the summit does not look straight.

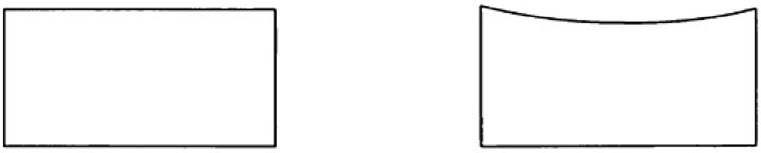

FIGURE 10.5

The next figure introduced will hardly improve matters. It is fortunate, indeed, that diagrams are not required for proofs. They might be quite misleading in hyperbolic geometry.

Definition 56. A quadrilateral containing three right angles is called a *Lambert Quadrilateral.*

Notation Rule 21. *The quadrilateral defined in Definition 56 will be denoted by:*

L.Q. $ABCD$

where the first three letters of the quadrilateral named will always represent the right angles.

As far as the definition is concerned it would be possible to refer to a square or a rectangle as a Lambert Quadrilateral. Once again it should be pointed out that in Euclidean geometry this is seldom done and, as the next theorem shows, in Hyperbolic geometry it cannot be done.

Theorem 134. In a L.Q. the fourth angle is acute.

Proof: Let $ABCD$ be a L.Q. with right angles at A, B, and C. Let E be a point such that $A*B*E$, and let F be a point such that $D*C*F$. Finally, let $B\text{–}A \cong B\text{–}E$ and $C\text{–}D \cong C\text{–}F$.

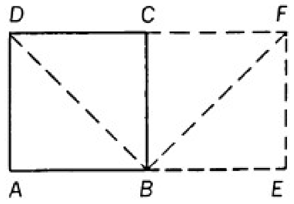

FIGURE 10.6

$\triangle DCB \cong \triangle FCB$ by SAS and thus their corresponding angles are congruent, as well as sides $D\text{–}B$ and $B\text{–}F$.

From Theorem 125 it follows that $\overrightarrow{BD}$ is between $\overrightarrow{BA}$ and $\overrightarrow{BC}$; it is also the case that $\overrightarrow{BF}$ is between $\overrightarrow{BC}$ and $\overrightarrow{BE}$.

It now follows that $\angle DBA \cong \angle FBE$ (why?); so $\triangle DBA \cong \triangle FBE$ by SAS, $\angle A \cong \angle E$, and $D\text{–}A \cong F\text{–}E$.

It was given that $\angle A$ is a right angle; it has been shown that $\angle A \cong \angle E$. Therefore, $\angle A$ and $\angle E$ are right angles.

By definition, it is now the case that quadrilateral $AEFD$ is a S.Q. and so by Theorem 133 $\angle ADC$ is acute. ●

It is now possible to prove the converse of Theorem 129; contrary to one's first impression, this is not a theorem from absolute geometry.

Theorem 135. If a line is perpendicular to both the base and summit of a S.Q., it joins the midpoints.

Proof: Left as an exercise (Hint: This statement is equivalent to "the line joining the midpoint of the base and summit of a S.Q. is the only line perpendicular to both of them" when used in conjunction with Theorems 129 and 134.)

The following theorem and its converse are very useful. It should be noted that they are about *any* convex quadrilaterals that have two right angles (and satisfy the other conditions).

Theorem 136. If, in a convex quadrilateral $ABCD$, the angles at A and B are right angles, and if $A\text{–}D < B\text{–}C$, then $\angle C < \angle D$.

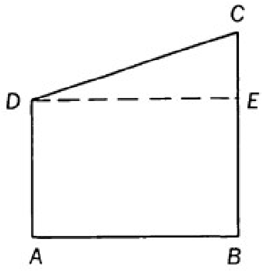

FIGURE 10.7

Proof: Since $A\text{–}D < B\text{–}C$, there exists a point E such that $B{*}E{*}C$ and $A\text{–}D \cong B\text{–}E$; but then quadrilateral $ABED$ is a S.Q., and from Theorem 132

$$\text{(a)}\quad \angle ADE \cong \angle BED$$

From the exterior angle theorem it follows that

$$\text{(b)}\quad \angle BCD < \angle BED$$

and from the definition of *less than*, that

$$\text{(c)}\quad \angle ADE < \angle ADC$$

Now, from Theorem 67 (Pre-Substitution) and lines (a) and (c), we have

$$\text{(d)}\quad \angle BED < \angle ADC$$

and from (b) and (d) together with Theorem 69 (Transitivity), it can be concluded that

$$\angle BCD < \angle ADC, \text{ that is, } \angle C < \angle D. \quad \bullet$$

Theorem 137. If, in a convex quadrilateral $ABCD$, the angles at A and at B are right angles, and if $\angle C < \angle D$, then $A\text{–}D < B\text{–}C$.

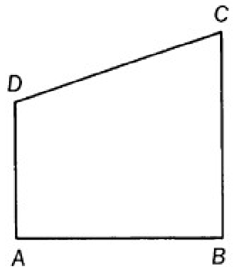

FIGURE 10.8

Proof: Suppose that $A\text{–}D \cong B\text{–}C$. Then, by definition, $ABCD$ is a *S.Q.*, and the assumption that $\angle C < \angle D$ contradicts Theorem 132.

Suppose $B\text{–}C < A\text{–}D$. Then, by Theorem 136, $\angle D < \angle C$, and this contradicts our hypothesis (by Theorem 66, the Trichotomy Theorem for angles).

Thus, by Theorem 57, the Trichotomy Theorem for segments, it is the case that $A\text{–}D < B\text{–}C$. ●

Theorem 138. In any convex quadrilateral $ABCD$, if $\angle A$ and $\angle B$ are right angles, and $\angle C \cong \angle D$, then the figure is a S.Q.

Proof: Left as an exercise.

EXERCISES 10.2

1. If a perpendicular is erected *at* any point *on* the side of a S.Q. it must intersect the opposite side. Answer true or false. If true, prove it; if false, give a counterexample.
2. If a perpendicular is erected *at* any point *on* the summit of a S.Q. it must intersect the base. Answer true or false. If true, prove it; if false, give a counterexample.
3. If a perpendicular is *dropped from* a point on a side of a S.Q. *to* the opposite side line, it must intersect the side. Answer true or false. If true, prove it; if false give, a counterexample.
4. Prove Theorem 131.
5. Prove Theorem 132.
6. Complete the proof of Theorem 133.
7. Prove Theorem 135.
8. Prove Theorem 138.
9. Prove that in a L. Q. the sides adjacent to the acute angle are greater than their respective opposite sides.
10. Prove that in a S.Q. the summit is greater than the base.

11. Prove that the diagonals of a S.Q. are congruent.

12. Prove that the diagonals of a S.Q. do not bisect each other.

13. Prove that the perpendicular bisector of the base of a S.Q. passes through the intersection of the diagonals.

14. Prove that if from the extremities of one side of a triangle, lines are drawn perpendicular to the line passing through the midpoints of the other two sides, a S.Q. is formed.

15. Prove that the perpendicular bisector of any side of a triangle is perpendicular to the line joining the midpoints of the other two sides.

*16. Prove that a line through the midpoint of one side of a triangle and perpendicular to the line that bisects a second side at right angles bisects the third side.

17. Prove that the line joining the midpoints of the equal sides of a S.Q. is perpendicular to the line joining the midpoints of the base and summit; prove that it bisects the diagonals.

18. Prove that the line joining the midpoints of the equal sides of a S.Q. does not pass through the intersection of the diagonals.

10.3 Congruent Quadrilaterals

Notation Rule 22: *By $ABCD \leftrightarrow EFGH$ we shall mean:*

$$\begin{array}{lll} A \leftrightarrow E & \angle A \leftrightarrow \angle E & A\text{–}B \leftrightarrow E\text{–}F \\ B \leftrightarrow F & \angle B \leftrightarrow \angle F & B\text{–}C \leftrightarrow F\text{–}G \\ C \leftrightarrow G & \angle C \leftrightarrow \angle G & C\text{–}D \leftrightarrow G\text{–}H \\ D \leftrightarrow H & \angle D \leftrightarrow \angle H & A\text{–}D \leftrightarrow E\text{–}H \end{array}$$

Definition 57. Given any two quadrilaterals $ABCD$, $EFGH$, if there exists at least one correspondence $ABCD \leftrightarrow WXYZ$, where W, X, Y, Z are E, F, G, H in some order such that

$$\begin{array}{ll} \angle A \cong \angle W & A\text{–}B \cong W\text{–}X \\ \angle B \cong \angle X & B\text{–}C \cong X\text{–}Y \\ \angle C \cong \angle Y & C\text{–}D \cong Y\text{–}Z \\ \angle D \cong \angle Z & A\text{–}D \cong W\text{–}Z \end{array}$$

then this correspondence is called a *congruent correspondence* or a *congruence.* The two quadrilaterals are called *congruent.*

Notation Rule 23: *If $ABCD \leftrightarrow EFGH$ is a congruent correspondence for quadrilaterals $ABCD$ and $EFGH$, this will be denoted by:*

$$ABCD \cong EFGH$$

Some of the techniques used to prove the following theorems are quite different from those used to prove most elementary congruence theorems in Euclidean geometry.

Theorem 139. If in L.Q.'s $ABCD$ and $EFGH$, $ABCD \leftrightarrow EFGH$, $\angle D \cong \angle H$ and, if any *one* of the following holds:

$$\text{(a)}\quad A{-}D \cong E{-}H \quad \text{or} \quad \text{(b)}\quad D{-}C \cong H{-}G$$

or

$$\text{(c)}\quad A{-}B \cong E{-}F \quad \text{or} \quad \text{(d)}\quad B{-}C \cong F{-}G$$

then, $ABCD \cong EFGH$.

Proof: The proofs of (a) and (b) are similar, as are the proofs of (c) and (d) but, as we shall see, the proofs of (a) and (c) are quite different.

Case (a). By hypothesis $A{-}D \cong E{-}H$. Suppose $D{-}C < H{-}G$. Then there exists a point I such that $H{*}I{*}G$ and $D{-}C \cong H{-}I$; $\triangle ADC \cong \triangle EHI$ by SAS.

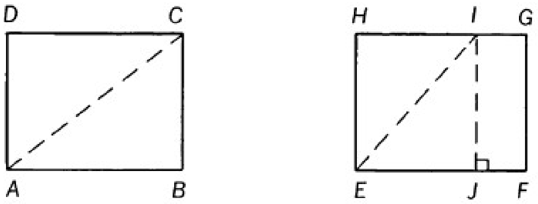

FIGURE 10.9

At I drop a perpendicular to line EF intersecting at a point J such that $E{*}J{*}F$ (follows from Theorem 128).

Now, $\overrightarrow{AC}$ is between $\overrightarrow{AD}$ and $\overrightarrow{AB}$; also $\overrightarrow{EI}$ is between $\overrightarrow{EH}$ and $\overrightarrow{EJ}$. (Why?) Therefore, $\triangle ABC \cong \triangle EJI$. (Why?)

Now $\angle DCA \cong \angle HIE$, $\angle ACB \cong \angle EIJ$; therefore, $\angle DCB \cong \angle HIJ$. Since $\angle C$ is a right angle, so is $\angle HIJ$, and hence so is $\angle JIG$. By construction, so is $\angle IJF$. Therefore, quadrilateral $IJFG$ has four right angles, contradicting Theorem 134.

A similar argument holds if $H{-}G < D{-}C$. Therefore, from the Trichotomy Theorem it follows that $D{-}C \cong H{-}G$.

It now follows that $\triangle ADC \cong \triangle EHG$; then, since $\overrightarrow{EG}$ is between $\overrightarrow{EH}$ and $\overrightarrow{EF}$, it follows by ASA (or SAA) that $\triangle ABC \cong \triangle EFG$.

Thus, $ABCD \cong EFGH$.

Case (c). By hypothesis, $A{-}B \cong E{-}F$. Let H' be a point such that $D{*}A{*}H'$ and $A{-}H' \cong E{-}H$. Then $\triangle BAH' \cong \triangle FEH$ (why?), and $H'{-}B \cong H{-}F$.

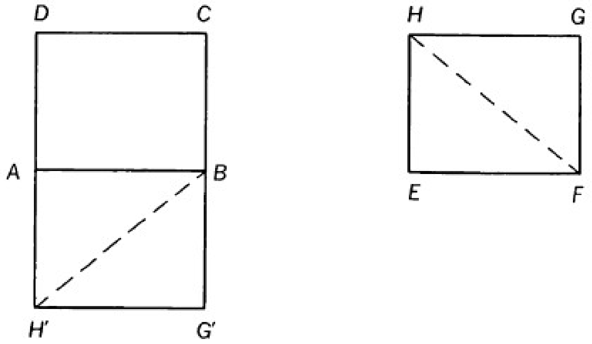

FIGURE 10.10

Let G' be a point such that $C*B*G'$ and $B\text{–}G' \cong F\text{–}G$. Join G', H'. Now $\overrightarrow{BH'}$ is between $\overrightarrow{BA}$ and $\overrightarrow{BG'}$ (why?) and $\overrightarrow{FH}$ is between $\overrightarrow{FE}$ and $\overrightarrow{FG}$. Thus, $\triangle BG'H' \cong \triangle FGH$. (Why?)

It now follows that $\angle AH'G' \cong \angle EHG$ and $ABG'H' \cong EFGH$. Therefore, by transitivity $\angle H' \cong \angle D$. Also $\angle G'$ and $\angle C$ are right angles. So by Theorem 138, $G'CDH'$ is a S.Q.

By definition of S.Q., $D\text{–}C \cong H'\text{–}G'$. By Theorem 135, $B\text{–}C \cong B\text{–}G'$, and $D\text{–}A \cong A\text{–}H'$. Hence, by transitivity and definition, $ABCD \cong EFGH$. ●

There are many ways to attempt the above proof, and because a Lambert Quadrilateral is actually being constructed, one must be wary not to assume what is being proved.

This theorem, once proved, provides an easy test for congruence of Lambert Quadrilaterals that can be used in the following proof about Saccheri Quadrilaterals:

Theorem 140. If in S.Q.'s $ABCD$ and $EFGH$, $ABCD \leftrightarrow EFGH$, $\angle D \cong \angle H$ and, if any *one* of the following holds:

(a) $C\text{–}D \cong G\text{–}H$ *or* (b) $A\text{–}B \cong E\text{–}F$ *or* (c) $B\text{–}C \cong F\text{–}G$

then $ABCD \cong EFGH$.

Proof:

Case (*a*). By hypothesis, $C\text{–}D \cong G\text{–}H$, $\angle D \cong \angle H$.

Suppose $H\text{–}E < D\text{–}A$. Then there exists a point I such that $D*I*A$ and $D\text{–}I \cong H\text{–}E$. Then $\triangle DIC \cong \triangle HEG$.

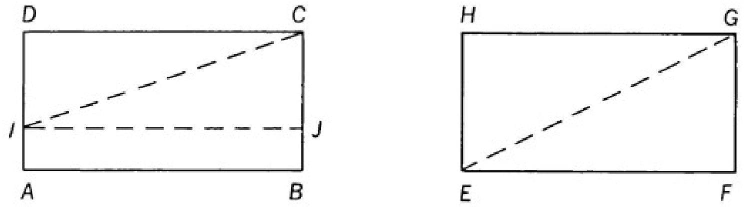

FIGURE 10.11

On $\overrightarrow{CB}$, let $C\text{–}J \cong G\text{–}F$. Then $\overrightarrow{CI}$ is between $\overrightarrow{CJ}$ and $\overrightarrow{CD}$. (Why?) Hence, $\triangle ICJ \cong \triangle EGF$. (Why?)

It now follows that $C{*}J{*}B$. (Why?)

Since it can be shown that $\angle DIJ$ and $\angle IJC$ are right angles, it follows that $\angle AIJ$ and $\angle BJI$ are right angles. This contradicts Theorem 134.

Similarly, if $D\text{–}A < H\text{–}E$. Therefore, $H\text{–}E \cong D\text{–}A$.

From this, it can be shown that $\triangle ADC \cong \triangle EHG$ and $\triangle ACB \cong \triangle EGF$, and thus finally that $ABCD \cong EFGH$.

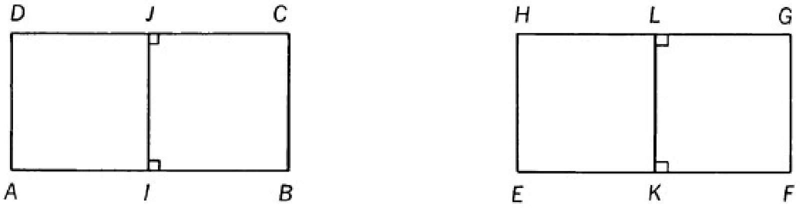

FIGURE 10.12

Case (*b*). This follows from constructing the perpendiculars at the midpoints of $A\text{–}B$ and $E\text{–}F$ and using Theorem 139, case (c).

Case (*c*). Follows as in Case (b) from Theorem 139, Case (b). ●

EXERCISES 10.3

1. Fill in the proofs of Theorems 139 and 140, Case (a).
2. Complete the proof of Theorem 140, Case (b).
3. Complete the proof of Theorem 140, Case (c).
4. If $ABCD$ and $EFGH$ are two L.Q.'s with acute angles at D and H, prove that:

(a) If $A\text{–}B \cong E\text{–}F$ and $B\text{–}C \cong F\text{–}G$, then $ABCD \cong EFGH$.

(b) If $D\text{–}A \cong H\text{–}E$ and $A\text{–}B \cong E\text{–}F$, then $ABCD \cong EFGH$.

(c) If $D\text{–}A \cong H\text{–}E$ and $B\text{–}C \cong F\text{–}G$, then $ABCD \cong EFGH$.

*(d) If $D\text{–}A \cong H\text{–}E$ and $D\text{–}C \cong H\text{–}G$, then $ABCD \cong EFGH$.

5. If $ABCD$ and $EFGH$ are S.Q.'s with acute angles at C, D, G, and H, prove that:

(a) If $A\text{–}B \cong E\text{–}F$ and if $B\text{–}C \cong F\text{–}G$, then $ABCD \cong EFGH$.
(b) If $A\text{–}B \cong E\text{–}F$ and if $C\text{–}D \cong G\text{–}H$, then $ABCD \cong EFGH$.
(c) If $B\text{–}C \cong F\text{–}G$ and if $C\text{–}D \cong G\text{–}H$, then $ABCD \cong EFGH$.

10.4 A Comparison of Hyperbolic and Euclidean Properties

In this section we will briefly survey some of the properties of hyperbolic geometry that contrast most strikingly with Euclidean properties. There will be no attempt to present this material formally. Some properties will be introduced by means of theorems, others will merely be mentioned or briefly discussed.

Parallels

In Definitions 51 and 52 we stated that in order for two rays to be parallel they must be *in the same direction*, and it was stated what that meant. Let us now refer to that direction as the *direction of parallelism*.

By now the reader must have anticipated the next theorem. It says, in effect, that parallel lines (rays) converge in the direction of parallelism.

Theorem 141. If $\overrightarrow{PR}$ and $\overrightarrow{QS}$ are any two parallel rays, and A, B, are points such that $P{*}A{*}B{*}R$, let C, D be the points where the perpendiculars from A and B to line QS intersect QS, then $B\text{–}D < A\text{–}C$.

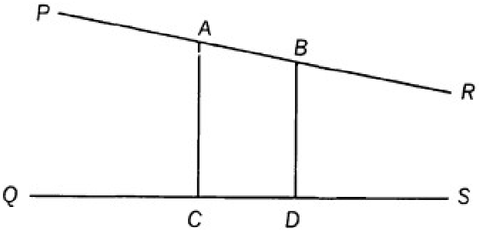

FIGURE 10.13

Proof: Because $\overrightarrow{PR}$ is parallel to $\overrightarrow{QS}$, so is $\overrightarrow{AR}$ and $\overrightarrow{BR}$. Then $\angle CAR$ and $\angle DBR$ are each acute angles.

But since $A{*}B{*}R$, it follows that $\angle DBA$, $\angle DBR$ form a linear pair and, hence, that $\angle DBA$ is obtuse.

Then in (convex?) quadrilateral $CDBA$ $\angle C$, $\angle D$ are right angles and $\angle CAB < \angle DBA$. So, by Theorem 137, $B\text{–}D < A\text{–}C$. ●

It should be immediately apparent from the proof of this theorem that if X is any point such that $A*B*X$, and Y is the foot of the perpendicular from X to line QS, then $X\text{–}Y < B\text{–}D$. This says that any segment "farther out" in the direction of parallelism is less than the preceding ones. But this does not imply that parallels become less than any length no matter how small; that is, that the distance between parallels converges to zero; or, that the lines are asymptotic. The next theorem, in effect, says just that.

Theorem 142. Let $X\text{–}Y$ be any segment whatsoever; then there exists a segment $W\text{–}Z$ such that W is on $\overrightarrow{PR}$, a parallel to QS, and $W\text{–}Z$ is a perpendicular to QS, and $W\text{–}Z < X\text{–}Y$.

Proof: Let $\overrightarrow{PR}$ and $\overrightarrow{QS}$ be parallel and PA perpendicular to QS. Let $X\text{–}Y$ be any segment whatsoever; then, if $P\text{–}A < X\text{–}Y$ we are through. If $P\text{–}A \cong X\text{–}Y$ then this theorem follows from Theorem 141. Suppose then, that $X\text{–}Y < P\text{–}A$.

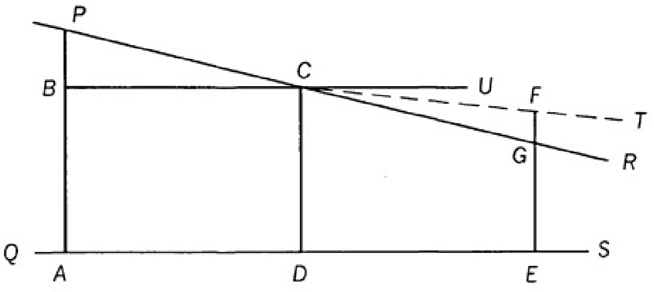

FIGURE 10.14

Let B be a point such that $A*B*P$ and $A\text{–}B \cong X\text{–}Y$. Through B let $\overrightarrow{BU}$ be perpendicular to PA and in the direction $\overrightarrow{QS}$. Then, by Theorem 119, $\overrightarrow{BU}$ intersects $\overrightarrow{PR}$ at some point, say C. Let CD be the perpendicular from C to QS.

Then $\angle RCD < \angle BCD$. (Why?) So let $\overrightarrow{CT}$ be such that $\angle BCD \cong \angle TCD$; then $\angle RCD < \angle TCD$.

Let E be a point such that $A*D*E$ and $A\text{–}D \cong D\text{–}E$, and let F be a point on $\overrightarrow{CT}$ such that $B\text{–}C \cong C\text{–}F$.

Now it can be shown that $F\text{–}E \cong A\text{–}B$, and FE is perpendicular to QS

(left as an exercise). Furthermore, $\overrightarrow{PC}$ must intersect $F\text{–}E$ at some point, say G. (Why?)

Thus $E\text{–}G < E\text{–}F$; $E\text{–}F \cong A\text{–}B$; $A\text{–}B \cong X\text{–}Y$. So $E\text{–}G < X\text{–}Y$, where G is a point on $\overrightarrow{PR}$ and EG is perpendicular to $\overrightarrow{QS}$. Hence $E\text{–}G$ is the segment $W\text{–}Z$. This completes the proof. ●

It should be apparent also that parallel rays diverge in the opposite direction and become larger than any given segment. This could be proved now, but we leave this as an exercise and turn to other interesting implications of the theory of parallels.

While discussing the historical development of non-Euclidean geometries, we stated that in the new geometry there exists an *absolute unit* of length. A rigorous discussion of this concept lies beyond the synthetic approach, but the following intuitive explanation may help to clarify it.

Given points A, Y, P, and X, such that $A*Y*P*X$; and given parallels $\overrightarrow{AR}$, $\overrightarrow{YS}$, $\overrightarrow{PT}$, and $\overrightarrow{XU}$, it follows immediately from Theorem 120 that $\angle AXU < \angle APT < \angle AYS$. (See Figure 10.15.)

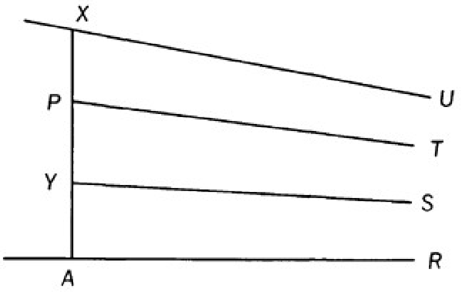

FIGURE 10.15

Furthermore, given two *T-V-T*'s $RABS$ and $R'CDS'$, such that $\angle B$ and $\angle D$ are right angles, then it follows immediately from Theorem 121 that if $A\text{–}B \cong C\text{–}D$, then $\angle A \cong \angle C$; and from Theorem 122 it follows that if $\angle A \cong \angle C$, then $A\text{–}B \cong C\text{–}D$. (See Figure 10.16.)

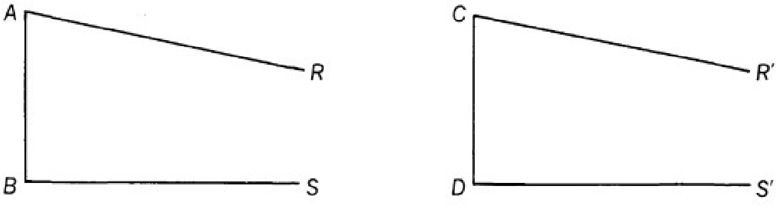

FIGURE 10.16

The following definition will make it easier to discuss this:

Definition 58. Given $\overrightarrow{PR}$ a parallel to m through P, and Q the intersection point of the perpendicular from P to m, then $\angle QPR$ is called *the angle of parallelism for P–Q.*

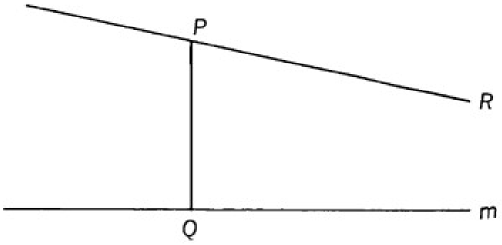

FIGURE 10.17

We can now say that the angles of parallelism corresponding to equal distances are equal, and conversely. Furthermore, as the distances become greater, the angle of parallelism becomes smaller, and as the distances become smaller, the angles of parallelism become larger. There is a functional relationship between the measure of the angle of parallelism $\angle QPR$ and the length of the segment P–Q; furthermore, to every acute angle there corresponds a distance for which the angle is the angle of parallelism.

In both Euclidean and hyperbolic geometries there is an absolute standard to which all angles can be compared, the right angle. No one needs to keep a right angle hidden in a vault at the Bureau of Standards to preserve it, for it can always be reconstructed. Thus, there exists a natural *unit* of measure (some given fractional part of a right angle) that could be reconstructed if it were ever lost. This is what is meant by saying that angles have an *absolute* unit of measure in both geometries.

In Euclidean geometry there is no absolute standard for units of length; they are quite arbitrary. However, once it has been determined in hyperbolic geometry that to every angle there corresponds a definite segment, namely the segment associated with that angle when it is regarded as an angle of parallelism, an interesting new property comes into being. From the unit of angular measure one can determine a corresponding unit of linear measure, a unit having a structural connection with the geometry and thus one that is an absolute unit of length.

Nonintersecting Nonparallel Lines

It has already been shown that if two lines have a common perpendicular they are nonintersecting and nonparallel. A proof, originated by

Hilbert, establishes the converse and occurs in most texts on hyperbolic geometry. Because the proof is long and complicated and does not introduce any new techniques that make its reproduction here worthwhile, we shall omit it and merely state the theorem.

Theorem 143. If two straight lines neither intersect nor are parallel, they must have a common perpendicular.

This is an *existence* theorem (in fact, Hilbert's proof actually shows how to construct such a line if one knows how to construct parallels). The *uniqueness* of the common perpendicular was established in effect in the proof of Theorem 134.

A property more interesting than the existence of a common perpendicular to two nonintersecting lines is:

Theorem 144. Let the common perpendicular to two nonintersecting lines m, n, meet at P, Q. Let A, B be points such that $P{*}A{*}B$ and let perpendiculars through A, B to n meet at C, D respectively, then

$$P\text{–}Q < A\text{–}C,\ A\text{–}C < B\text{–}D$$

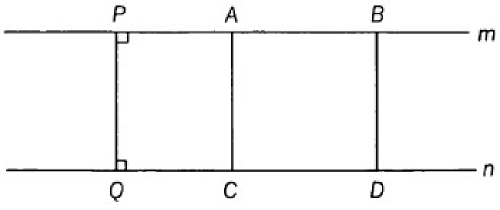

FIGURE 10.18

Proof: $PQCA$ is a L.Q. Hence, $\angle CAP$ is acute and, therefore, $P\text{–}Q < A\text{–}C$ by Theorem 137.

Because $\angle CAP$ is acute, $\angle CAB$ is obtuse. Since quadrilateral $PQDB$ is a L.Q., $\angle DBP$ is acute. But $\angle DBP = \angle DBA$. Hence, in (convex?) quadrilateral $CDBA$, $\angle DBA < \angle CAB$.

Therefore, $A\text{–}C < B\text{–}D$ by Theorem 137.

A similar argument holds if the points are on the opposite sides of line PQ. ●

This theorem, in effect, shows that nonintersecting nonparallel lines diverge as the distance from the common parallel increases. It can also be shown that the distance apart becomes greater than any arbitrarily chosen segment. Thus, it would seem that nonintersecting lines are as shown in Figure 10.19.

Hilbert, establishes the converse and occurs in most texts on hyperbolic geometry. Because the proof is long and complicated and does not introduce any new techniques that make its reproduction here worthwhile, we shall omit it and merely state the theorem.

Theorem 143. If two straight lines neither intersect nor are parallel, they must have a common perpendicular.

This is an *existence* theorem (in fact, Hilbert's proof actually shows how to construct such a line if one knows how to construct parallels). The *uniqueness* of the common perpendicular was established in effect in the proof of Theorem 134.

A property more interesting than the existence of a common perpendicular to two nonintersecting lines is:

Theorem 144. Let the common perpendicular to two nonintersecting lines m, n, meet at P, Q. Let A, B be points such that $P{*}A{*}B$ and let perpendiculars through A, B to n meet at C, D respectively, then

$$P\text{–}Q < A\text{–}C,\ A\text{–}C < B\text{–}D$$

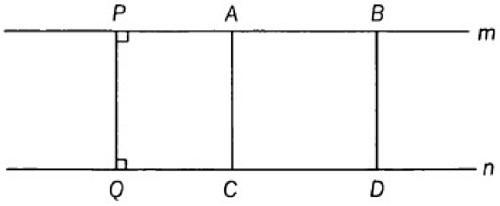

FIGURE 10.18

Proof: $PQCA$ is a L.Q. Hence, $\angle CAP$ is acute and, therefore, $P\text{–}Q < A\text{–}C$ by Theorem 137.

Because $\angle CAP$ is acute, $\angle CAB$ is obtuse. Since quadrilateral $PQDB$ is a L.Q., $\angle DBP$ is acute. But $\angle DBP = \angle DBA$. Hence, in (convex?) quadrilateral $CDBA$, $\angle DBA < \angle CAB$.

Therefore, $A\text{–}C < B\text{–}D$ by Theorem 137.

A similar argument holds if the points are on the opposite sides of line PQ. ●

This theorem, in effect, shows that nonintersecting nonparallel lines diverge as the distance from the common parallel increases. It can also be shown that the distance apart becomes greater than any arbitrarily chosen segment. Thus, it would seem that nonintersecting lines are as shown in Figure 10.19.

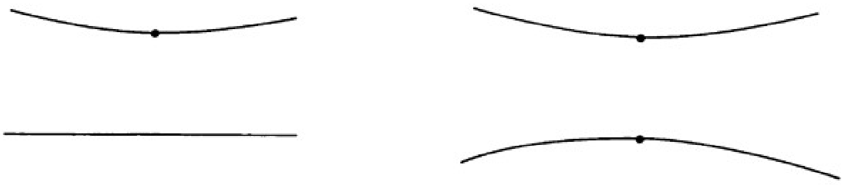

FIGURE 10.19

Triangles

As previously stated, there are many interesting concepts in hyperbolic geometry that one might pursue in discussing triangles. We have chosen to omit discussions of area and defects of triangles, but several properties occur in this geometry which, although not well suited to the synthetic approach, should not be ignored. Accordingly, the remainder of the theorems will illustrate these properties.

Definition 59. Any *three* angles $\angle A$, $\angle B$, and $\angle C$ are said to be *taken together less than two right angles*, iff:

(a) $m(\angle X) + m(\angle Y) = m(\angle Z)$ exists, where $\angle X$, $\angle Y$ are any two of the three angles; and

(b) $\angle V$ and $\angle W$ are two angles taken together less than two right angles, where $\angle V$ is some angle of the set $m(\angle Z)$ and $\angle W$ is the remaining one of the three angles.

Theorem 145. The three angles of every right triangle are taken together less than two right angles.

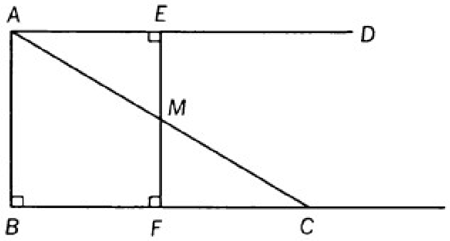

FIGURE 10.20

Proof: Let ABC be any triangle with a right angle at B. At A, on the opposite side of line AC from B, let $\angle CAD \cong \angle BCA$. Let M be the midpoint of A–C, and lines ME and MF the perpendiculars from M to AD and BC, respectively.

Then $\triangle FCM \cong \triangle EAM$ by SAA and, therefore, $\angle AME \cong \angle CMF$. But $\angle CMF$, $\angle FMA$ form a linear pair; therefore, $\angle AME$, $\angle FMA$ are supplementary. Since they are adjacent, by Theorem 62, Corollary 3, they form a linear pair.

Thus, $BFEA$ is a quadrilateral with right angles at B, F, and E. Hence, its fourth angle is acute. But $m(\angle BAE) = m(\angle BAC) + m(\angle BCA)$.

Therefore, $\angle B$, $\angle A'$, and $\angle C$ of triangle ABC are taken together less than two right angles. ●

Theorem 146. The three angles of *any* triangle are taken together less than two right angles.

Proof: Let ABC be any triangle. By Theorem 91, at least two of its angles are acute, say A and B.

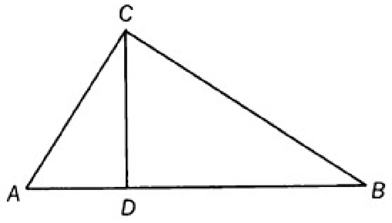

FIGURE 10.21

Then a line through C perpendicular to AB must intersect A–B at some point D. (Why?)

Therefore, C–D divides triangle ABC into two right triangles ADC and BDC.

From the preceding theorem, $m(\angle DAC) + m(\angle ACD) = m(\angle M)$ and $m(\angle M) < m(\angle X)$ where X is any right angle.

And $m(\angle DBC) + m(\angle DCB) = m(\angle N)$, and $m(\angle N) < m(\angle X)$.

Therefore, $\angle M$ and $\angle N$ are taken together less than two right angles. ●

These results, strange as they are, could have been anticipated from the discussion of the history of attempts to prove the Fifth. For if the statement:

The sum of the angles of any triangle equals two right angles.

is equivalent to the Parallel Postulate, then when one statement is denied so is the other. Of course, whether the sum was to be less than or greater than two right angles still had to be determined.

The last of the properties to be discussed in this section may also have been anticipated—a clue was given by Theorem 122, where the congruence of the angles of two T-V-T triangles implied the congruence of the sides. The property is introduced below as statement (S). Unfortunately, it cannot be introduced as a theorem because the proof does not lend itself to the synthetic method. In such a proof we would be required to say that:

The sum of four angles (of a quadrilateral) is less than 360 degrees (four right angles).

There is no easy way, in the synthetic approach, to express a statement equivalent to this. The problem is not only to find a definition but to find a definition that is usable.

If such a definition were available, then the proof of the following statement would be relatively easy.

(S) If two triangles ABC and DEF are such that $ABC \leftrightarrow DEF$, $\angle A \cong \angle D$, $\angle B \cong \angle E$, $\angle C \cong \angle F$, then $\triangle ABC \cong \triangle DEF$.

This statement introduces one of the most astounding properties of hyperbolic geometry. In effect, it says that there is no such thing as two figures being similar but not congruent. Thus, for a photograph to resemble its subject it would have to be a lifesize photograph: moreover, all the fields that depend upon similarity and proportion would be drastically altered. Consider what would happen to painting, designing, drafting, and architecture. Consider what would happen to the world around us. It would be a very strange new world.

Yet such a world is a possible one. The last chapter will explain how it might even be that this geometry most closely describes the space world around us.

EXERCISES 10.4

1. In the proof of Theorem 142:

   (a) prove that $\overrightarrow{CT}$ is between $\overrightarrow{CU}$ and $\overrightarrow{CR}$;
   (b) prove that $E\text{-}F \cong B\text{-}A$, and $\angle DEF$ is a right angle.

2. Complete the proof of Theorem 146.

3. Prove that parallel rays diverge in the direction opposite to the direction of parallelism.

4. Try to define what it means to say that the sum of four angles is less than (or equal to) four right angles.

5. Assuming one has the definition of exercise 4, prove statement (S) of the text.

Which of the following statements are true in *both* Euclidean and hyperbolic geometry. Explain.

6. There exist equilateral quadrilaterals.

7. There exist parallelograms.

8. Two lines are parallel if they have no points in common.

9. If two lines are perpendicular to the same line, then they are parallel.

10. The perpendicular to a given line from a point not on it is unique.

11. The exterior angle of a triangle is greater than the opposite interior angle.

12. Given a line and a point not on the line, there exists at least one line which passes through the given point and is parallel to the given line.

13. If two sides of a triangle are not congruent, then the angles opposite them are not congruent and the greater angle is opposite the longer side.

14. The opposite sides of a parallelogram are equal.

15. All straight angles are equal to two right angles.

16. Given two lines and a transversal, if a pair of corresponding angles are congruent, then a pair of alternate interior angles are congruent.

17. If a S.Q. $ABCD$ has right angles at A and B, then the angles at C and D are congruent to each other.

18. All squares have four equal angles.

19. The Pythagorean Theorem holds.

5-   2 N3

11 A Model World

From the list of theorems in the last two chapters, one may choose numerous denials of the Euclidean parallel axiom and its equivalent forms:

1. Through a point outside a given line, more than one parallel to the given line exists.
2. If two lines are cut by a transversal such that the interior angles on the same side of the transversal are, taken together, less than two right angles, the lines do not necessarily meet on that side.
3. Parallel lines are not everywhere equidistant.
4. The sum of the angles of any triangle is less than two right angles.

These are only a few. Each denies some statement of Euclidean geometry; but the statements on the list are consistent with each other. Or so we are told.

How do we know? How do we know that neither Saccheri nor Lambert actually reached a contradiction? How do we know that the system of Bolyai-Lobachevsky is free from contradictions, that no theorem derived contradicts another, and that no such theorems will ever be found?

It is often said that Bolyai and Lobachevsky proved the independence of the parallel postulate but this is not quite accurate. It was not until some years later that a model was found for their system. Perhaps the first to do so was E. Beltrami (1835–1900). Another model, the one we shall discuss, was presented by H. Poincaré (1854–1912) in his work *Science and Hypothesis*. Both of these models are often credited to Klein, who discussed them in relation to projective geometry.

11.1 A Model

We shall now return to the Euclidean plane and assume the full extent of its properties. The purpose is to construct a model for hyperbolic geometry from a part of that plane.

Consider a circle, which will be called the *fundamental circle*. A Euclidean point will be considered a point in this model if and only if it is interior to the fundamental circle. Points on the circle are to be "points at infinity."

Consider now a circle that cuts the fundamental circle orthogonally; that is, in such a manner that the tangents to each circle at the points of intersection are perpendicular to each other. By a "straight line" we shall mean that *part* of such a circle that is interior to the fundamental circle.

By various techniques of modern Euclidean geometry, many interesting properties of such "lines" can be derived. For example, it can be shown that through two points interior to the fundamental circle, exactly one circle exists that is orthogonal to the fundamental circle; and, that two circles orthogonal to the fundamental circle can intersect in at most one point interior to the fundamental circle.

Furthermore, a distance function can be defined in such a way that the distance between any interior point and points nearer and nearer to the fundamental circle grows larger without bound. Thus this model, in effect, may be regarded as infinite in extent.

In such a model it is actually easy to "see" some of the properties that seemed so strange and were impossible to diagram in a strictly Euclidean framework.

Figure 11.1 shows two parallels PR and PS through a point P not on a line m. It indicates the angle θ that these two lines make with each other.

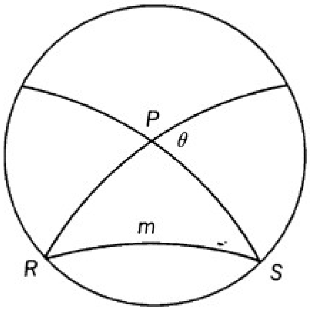

FIGURE 11.1

Figure 11.2 shows a T-V-T $RABS$, in which $R = S$ (a point at infinity). It also shows an ordinary triangle ABD in which the sum of the angles are apparently less than two right angles.

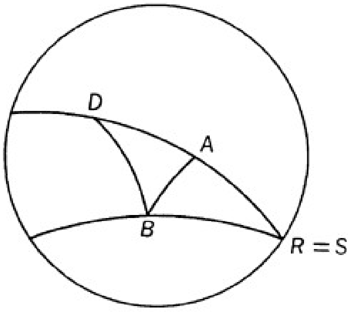

FIGURE 11.2

Figure 11.3 shows a S.Q. $ABCD$ with right angles at A and at B; and a L.Q. $BADE$ with right angles at B, A, and D.

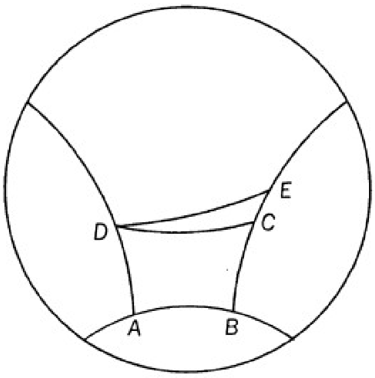

FIGURE 11.3

What makes this model so valuable is not so much that it is easy to diagram the results but that all the properties of hyperbolic geometry can be rigorously established in it; that it can easily be generalized to three dimensions by taking a fundamental sphere and spheres orthogonal to it; and, finally, that all of these results are actually being obtained in Euclidean geometry. The model exists in the Euclidean plane (or space) although it is a model for hyperbolic geometry.

The model, therefore, establishes a relative test for the consistency of hyperbolic geometry. That is, hyperbolic geometry is as consistent as Euclidean geometry; a contradiction could arise only if it already existed in the Euclidean model. It is a matter of fact that over the centuries no one has found an inconsistency in Euclidean geometry; therefore, it is very likely that there is none. This is not a very satisfactory test for consistency but it is the best one we have. But whether or not there exists an absolute test for the consistency of Euclidean geometry is irrelevant to our purposes. The main result of the model is that it shows that hyperbolic geometry is on as firm a logical base as Euclidean geometry; furthermore, it shows once and for all that the Parallel Postulate of Euclidean geometry is independent of the others.

However, the existence of the model also raises new questions. For, if they are both shown to be consistent, how does one decide which is the "true" geometry? Which geometry better describes the space world around us?

11.2 A Model World

Imagine a world which is a large sphere with the property that the temperature changes from point to point within the sphere. As one approaches the center of this sphere the temperature becomes hot and as one approaches the boundary of the sphere the temperature becomes very cold, approaching absolute zero. Furthermore, suppose that all material objects (including the inhabitants of this world) are extremely sensitive to changes in temperature and change instantaneously in size with each change in temperature in such a manner that they grow larger or indefinitely smaller as the temperature increases or decreases, respectively.

To an inhabitant of such a world it would seem to be of infinite extent, for as he approached the boundary of his world he would become smaller and smaller. To reach the boundary would require an infinite number of steps, and he would be as sure that his world was infinite in extent as we seem to be in regard to ours. There would be no way for him to become aware of his situation because any yardstick he carried with him would change in the same proportion.

It can be shown rigorously (using the calculus of variations) that for an inhabitant of such a world the shortest distance between two points would be along the arc of a circle that cuts the bounding sphere orthogonally. This is plausible also, for as he walked from one point to another and if he followed a path which swerved toward the center, his steps would be longer there; thus this path would give a smaller number of steps.

Imagine yet another fact about this world, namely, that light travels along the "shortest paths" along the arcs of circles orthogonal to the bounding sphere. Then, if a man walked toward an object following the shortest path, these shortest paths would actually look straight to him.

What would some of the other properties of this world be? The angle θ shown in Figure 11.1 might very well be visible to the inhabitants. But this angle can be shown to decrease as the point P and line m approach the center of the bounding sphere. Or, to put it another way, if the point P and line m are at a given distance from the center of the sphere, the angle θ decreases indefinitely as the radius of the bounding sphere increases. Thus, the angle θ may be made very small indeed.

Suppose now that Earth is at the center of such a sphere and that the radius of the sphere is so large that the angle θ is smaller than any instrument of man can detect. *In such a situation, the physical world around us would differ in no respect from that to which we are accustomed. But the geometry of Lobachevsky would apply to this world as legitimately as the geometry of Euclid.*

This, then, creates a paradox. If θ is non-existent, we are living in a Euclidean world; if θ exists, no matter how small, we are living in a Lobachevskian world. But how can we ever know that the angle θ is not so small that it remains undetectable even though present? How can we know which geometry is the one that actually describes the world around us?

11.3 Is Euclidean Geometry True?

Modern physics suggests that our world is more likely to be a non-Euclidean one than a Euclidean one, although the particular geometry that physicists have adopted is a modification of Riemann's geometry rather than that of Lobachevsky. But this is not what we want to stress here.

As far as mathematics is concerned, the question as to which geometry is the true one is not merely totally irrelevant but meaningless. As Poincaré says, to ask which is true is like asking which form of measurement is more correct, centimeters or inches? Is the polar coordinate system the "true" one or is it the rectangular system? These are meaningless questions.

This is not to suggest that mathematics need not keep in touch with reality, for almost everyone would agree that a mathematics divorced from reality would soon become sterile. But this is quite different from being concerned with "truth." Rather let us ask which geometry is the most convenient. To this there is a simple answer: Euclidean geometry is the simplest and most convenient to use and shall probably always be used in elementary applications.

This does not mean, however, that no practical value can be found in studying other geometries. All of the geometries, finite and infinite, Euclidean and non-Euclidean, are worthy of investigation. This is so even if our prime objective is to obtain the "truest" geometry, the geometry with the widest range of applications. For the history of mathematics teaches us that some of the most useful results in mathematics have often come from pursuits having no apparent "useful" purpose. We have seen an illustration of this in the unexpectedly rich results that poured forth when mathematicians attempted to answer a seemingly innocent question: can Euclid's Fifth postulate be proved from the others?

8.2 Analogy with Riemannian Geometry

There is an interesting analogy between formula (8.4) (or (8.15)) and H. Weyl's formula [Wey3] for the volume of the tubular ε-neighborhood of a compact, n-dimensional Riemannian submanifold of Euclidean space $\mathbb{R}^d$. Indeed, by [BergGo, Theorem 6.9.9, p. 235], this volume is given by the formula

$$V_M(\varepsilon) = a_0\varepsilon^{d-n} + a_1\varepsilon^{d-n+1} + \cdots + a_n\varepsilon^d. \tag{8.23}$$

When $V_M(\varepsilon)$ is the volume of the two-sided ε-neighborhood, the odd-numbered coefficients $a_1, a_3, \ldots$ all vanish, and for $j = 0, 1, 2, \ldots$, the even numbered coefficient a_{2j} is given by

$$a_{2j} = \frac{1}{d-n+2j}\int_M K_{2j}\delta, \tag{8.24}$$

where K_{2j} is a universal j-th degree polynomial in the curvature tensor of M, and δ is the canonical density on M (see [BergGo, Proposition 6.6.1, p. 214]). Thus, formula (8.23) is a polynomial in ε whose coefficients (8.24) are expressed in terms of the Weyl curvatures in different (integer) dimensions.

If $V_M(\varepsilon)$ is the volume of the one-sided ε-neighborhood (which corresponds more closely to our definition of $V(\varepsilon)$), then the counterpart of (8.23) still holds. In that case, the odd coefficients do not necessarily vanish. We refer to [BergGo], Sections 6.6–6.9, and especially Section 6.9.8 and Theorem 6.9.9, and also to [Gra], for a much more detailed discussion and various helpful examples. For additional references, see also the endnotes in Section 8.5.

In the explicit formula (8.4) (or (8.15)), the volume $V(\varepsilon)$ is expressed as a sum of terms $\varepsilon^{1-\omega}$, where ω ranges over the visible complex dimensions. This suggests that the complex dimensions of fractal strings and the associated residues[7] could have a direct geometric interpretation. The work [Pe2] and [LapPe2–4, LapPeWi1–3] indicates a close relationship to some aspects of geometric measure theory [Fed1, 2] and a possible new notion of fractal curvature measures indexed by the underlying complex dimensions, both in the present one-dimensional context of fractal strings and in higher dimensions. See Section 13.1 for a discussion of the above work.

Remark 8.12. The Weyl curvatures occurring in Weyl's tube formula were shown in [Wey3] to be intrinsic to the submanifold. One of them is closely tied to the notion of Euler characteristic and hence to the Gauss–Bonnet formula (or its higher-dimensional counterpart, due to Chern).

After Goldbach and his influence on Euler, we turn to Gauss, who, among the large number of mathematicians with whom Riemann was in contact, was certainly the most influential on him.[9] We shall see in the various sections of the present chapter that this influence was crucial for what concerns the fields of complex analysis, elliptic integrals, topology, differential geometry—the same list as for Euler's influence on Riemann—and also for what concerns his ideas on space. There are other topics in mathematics and physics which were central in the work of Riemann and where he used ideas he learned from Gauss: the Dirichlet principle, magnetism, etc.; they are addressed in several other chapters of the present book.

The first contact between Gauss and Riemann took place probably in 1846, before Gauss became officially Riemann's mentor. In that year, in a letter to his father dated November 5 and translated in [233], Riemann informs the latter about the courses he plans to follow, and among them he mentions a course by Gauss on "the theory of least squares."[10] During his two year stay in Berlin (1847–1849), Riemann continued to study thoroughly Gauss's papers. In another letter to his father, dated May 30, 1849, he writes (translation in [233]):

> Dirichlet has arranged to me to have access to the library. Without his assistance, I fear there would have been obstacles. I am usually in the reading room by nine in the morning, to read two papers by Gauss that are not available anywhere else. I have looked fruitlessly for a long time in the catalog of the royal library for another work of Gauss, which won the Copenhagen prize, and finally just got it through Dr. Dale of the Observatory. I am still studying it.

During the same stay in Berlin, Riemann followed lectures by Dirichlet on topics related to Gauss's works. He writes to his father (letter without date, quoted in [233]):

> My own course of specialization is the one with Dirichlet; he lectures on an area of mathematics to which Gauss owes his entire reputation. I have applied myself very seriously to this subject, not without success, I hope.

Regarding his written production, Riemann endorsed Gauss' principle: *pauca sed matura* (few but ripe).

Riemann, as a child, liked history. In a letter to his father, dated May 3, 1840 (he was 14), he complains about the fact that at his Gymnasium there were fewer

---

[9] Some historians of mathematics claimed that when Riemann enrolled the University of Göttingen, as a doctoral student of Gauss, the latter was old and in poor health, and that furthermore, he disliked teaching. From this, they deduced that Gauss's influence on Riemann was limited. This is in contradiction with the scope and the variety of the mathematical ideas of Riemann for which he stated, in one way or another, but often explicitly, that he got them under the direct influence of Gauss or by reading his works. The influence of a mathematician is not measured by the time spent talking with him or reading his works. Gauss died the year after Riemann obtained his habilitation, but his imprint on him was permanent.

[10] The other courses are on the Cultural History of Greece and Rome, Theology, Recent Church history, General Physiology and Definite Integrals. Riemann had also the possibility to choose courses among Probability, Mineralogy and General Natural History. He adds: "The most useful to me will be mineralogy. Unfortunately it conflicts with Gauss's lecture, since it is scheduled at 10 o'clock, and so I'd be able to attend only if Gauss moved his lecture forward, otherwise it looks like it won't be possible. General Natural History would be very interesting, and I would certainly attend, if along with everything else I had enough money.".

integrals of algebraic functions, is analyzed in Chap. 4 of the present volume, written by Houzel [141].

Section 5 is concerned with the so-called Gauss hypergeometric series. These series, in various forms, were studied by Euler in his *Institutiones calculi integralis* (Foundations of integral calculus), a treatise in three volumes [92] (1768–1770), and in several other papers by him, and by Gauss. The hypergeometric series is a family of functions of the form

$$1+\frac{\alpha\beta}{1.\gamma}x+\frac{\alpha(\alpha+1)\beta(\beta+1)}{1.2\gamma(\gamma+1)}x^2+\frac{\alpha(\alpha+1)(\alpha+2)\beta(\beta+1)(\beta+2)}{1.2.3\gamma(\gamma+1)(\gamma+2)}x^3+\dots$$

where α, β, γ are parameters and where the variable is x.

Gauss considered that almost any transcendental function is obtained from a hypergeometric series by assigning special values to the parameters. By providing such a broad class of functions, the introduction of the hypergeometric series in the field of analysis opened up new paths. Besides Euler and Gauss, the predecessors of Riemann in this field include Pfaff and Kummer.

In Sect. 6, we deal with the zeta function. The history of this function is sometimes traced back to the work of Pietro Mengoli (1625–1686) on the problem of finding the value of the infinite series of inverses of squares of integers. Indeed, it is reasonable to assume that questions about this series were accompanied by questions about the series of inverses of cubes and other powers. But it was Euler again who studied $\sum_{1}^{\infty}\frac{1}{n^s}$ as a function of s (for s real), establishing the functional equation that it satisfies, and the relation with prime numbers. This was the starting point of Riemann's investigations on what became later known as the Riemann zeta function.

In Sect. 7, we make a quick review of some works done by Riemann's predecessors on the notion of space. This is essentially a philosophical debate, but it has a direct impact on mathematics and in particular on Riemann's work on geometry, more especially on his habilitation dissertation. It is in his reflections on space that Riemann introduced in mathematics the notion of Mannigfaltigkeit, which he borrowed from the philosophical literature. This notion reflects Riemann's multi-faced view on space, and it is an ancestor of the modern notion of manifold. Our review of space is necessarily very sketchy, since this notion is one of the most fundamental notions of philosophy, and talking seriously about it would require a whole essay. In particular, there is a lot to say on the philosophy of space in the works of Newton, Euler and Riemann and the comparison between them, but it is not possible to do it in the scope of the present chapter. Our intent here is just to indicate some aspects of the notion of space as it appears in the works of these authors and those of some other philosophers, including Aristotle, Descartes and Kant, and, as much as possible in a short survey, to give some hints on the context in which they emerge.

It is also important to say that the effect of this discussion on space goes far beyond the limits of philosophy. Euler's theories of physics are strongly permeated with his philosophical ideas on space. Gauss's differential geometry was motivated

;. 5 6

De repraesentatione superficiei sphaericae super plano (On the representation of spherical surfaces on a plane) [104], *De proiectione geographica superficiei sphaericae* (On the geographical projections of spherical surfaces) [105], and *De proiectione geographica Deslisliana in mappa generali imperii russici usitata* (On Delisle's geographic projection used in the general map of the Russian empire) [106]. The three memoirs were published in 1777. In the development of the theory, he used complex numbers to represent angle-preserving maps. Lagrange also studied angle-preserving maps, in his memoir *Sur la construction des cartes géographiques* (On the construction of geographical maps) [165], published in 1779.

In fact, the notion of angle-preserving map can be traced back to Greek antiquity, see the survey [194]. We already recalled that Euler, in his didactical treatise *Introductio in analysin infinitorum*, refers explicitly to functions in which the variable is a complex number. De Moivre, already in 1730, considered polynomials defined on the complex plane, and it is conceivable that other mathematicians before him did the same [182]. Remmert, who, besides being a specialist of complex analysis, is a highly respected historian in this field, writes in his *Theory of complex variables* [213] that the theory was born at the moment when Gauss sent a letter to Bessel, dated December 18, 1811, in which he writes[24]:

> At the beginning I would ask anyone who wants to introduce a new function in analysis to clarify whether he intends to confine it to real magnitudes (real values of the argument) and regard the imaginary values as just vestigial—or whether he subscribes to my fundamental proposition that in the realm of magnitudes the imaginary ones $a + b\sqrt{-1} = a + bi$ have to be regarded as enjoying equal rights with the real ones. We are not talking about practical utility here; rather analysis is, to my mind, a self-sufficient science. It would lose immeasurably in beauty and symmetry from the rejection of any fictive magnitudes. At each stage truths, which otherwise are quite generally valid, would have to be encumbered with all sorts of qualifications.

In fact, the letter also shows that at that time Gauss was already aware of the concept of complex integration, including Cauchy's integral theorem; cf. [126] Vol. 8, p. 90–92.

Cauchy, in his *Cours d'analyse* [34] (1821), starts by defining functions of real variables (p. 19), and then passes to complex variables. There are two distinct definitions in the real case, for functions of one or several variables:

> When variable quantities are so tied to each other that, given the value of one of them, we can deduce the values of all the others, we usually conceive these various quantities expressed in terms of one of them, which then bears the name *independent variable*; and the other quantities expressed in terms of the independent variable are what we call functions of that variable.
>
> When variable quantities are so tied to each other that, given the values of some of them, we can deduce the values of all the others, we usually conceive these various quantities expressed in terms of several of them, which then bear the name *independent variables*; and the remaining quantities expressed in terms of the independent variables, are what we call functions of these same variables.[25]

---

[24] The translation is Remmert's; cf. [213] p. 1.

[25] Lorsque des quantités variables sont tellement liées entre elles que, la valeur de l'une d'elles étant donnée, on puisse en conclure les valeurs de toutes les autres, on conçoit d'ordinaire ces

It was only at the publication of Gauss's *Collected Works*,[42] containing in particular his famous notebook, that it became clear that Gauss's assertion concerning the fact that he had discovered before Abel most of the properties of elliptic functions, including their double periodicity, was correct. One of the first results of Abel concerns integrals of arcs of lemniscate, a curve which he showed to be divisible by ruler and compass into n equal parts, for the same values of n for which the circle is divisible into n equal parts. The same result was stated without proof in Gauss's *Disquisitiones arithmeticae* [121].

Abel's first major results on elliptic functions are contained in his 1827 paper *Recherches sur les fonctions elliptiques* (Researches on elliptic functions) [1]. He explains there the double periodicity of these functions, as well as their multiplication and division properties. The analogy with circular functions is again highlighted. At the beginning of his paper, Abel talks about his famous predecessors, Euler, Lagrange and Legendre. He writes (p. 101):

> The first idea of these [elliptic] functions were given by the immortal Euler, who showed that the separable equation
>
> $$\frac{\partial x}{\sqrt{\alpha+\beta x+\gamma x^2+\delta x^3+\epsilon x^4}}+\frac{\partial y}{\sqrt{\alpha+\beta y+\gamma y^2+\delta y^3+\epsilon y^4}}=0$$
>
> is algebraically integrable. After Euler, Lagrange added something, when he gave his elegant theory of the transformation of the integral
>
> $$\int\frac{R\,dx}{\sqrt{(1-p^2x^2)(1-q^2x^2)}},$$
>
> where R is a rational function of x. But the first, if I am not mistaken, who went thoroughly into the nature of these functions, is Mr. Legendre, who, first in a memoir on elliptic functions, and then in his excellent *Exercices de mathématiques*, developed numerous elegant properties of these functions, and showed their usefulness.[43]

Riemann was already interested in elliptic functions while he was a student in Berlin. Klein, in his *Development of mathematics in the 19th century* [162] (Chap-

---

[42] Gauss's collected works, *Carl Friedrich Gauss' Werke*, in twelve volumes, were published between 1863 and 1929.

[43] La première idée de ces fonctions a été donnée par l'immortel Euler, en démontrant que l'équation séparée

$$\frac{\partial x}{\sqrt{\alpha+\beta x+\gamma x^2+\delta x^3+\epsilon x^4}}+\frac{\partial y}{\sqrt{\alpha+\beta y+\gamma y^2+\delta y^3+\epsilon y^4}}=0$$

est intégrable algébriquement. Après Euler, Lagrange y a ajouté quelque chose, en donnant son élégante théorie de la transformation de l'intégrale

$$\int\frac{R\,dx}{\sqrt{(1-p^2x^2)(1-q^2x^2)}},$$

où R est une fonction rationnelle de x. Mais le premier, et si je ne me trompe, le seul, qui ait approfondi la nature de ces fonctions, est M. Legendre, qui d'abord dans un mémoire sur les fonctions elliptiques, et ensuite dans ses excellents exercices de mathématiques, a développé nombre de propriétés élégantes de ces fonctions, et a montré leur application.

;. 5886 9,1 .

5 Hypergeometric Series

The theory of the hypergeometric series is another topic which Riemann tackled and whose roots involve in an essential way the works of Euler and Gauss. Riemann's main paper on the subject is *Beiträge zur Theorie der durch die Gauss'sche Reihe* $F(\alpha, \beta, \gamma, x)$ *darstellbaren Functionen* (Contribution to the theory of functions representable by Gauss's series $F(\alpha, \beta, \gamma, x)$) [222], published in 1857. The work in this paper was used by Riemann later in his development of the theory of analytic differential equations. There are also fragments on the same subject published in Riemann's *Collected works.*

The hypergeometric series is a function of the form

$$F(\alpha, \beta, \gamma, x) = 1 + \frac{\alpha\beta}{1.\gamma}x + \frac{\alpha(\alpha+1)\beta(\beta+1)}{1.2\gamma(\gamma+1)}x^2 + \frac{\alpha(\alpha+1)(\alpha+2)\beta(\beta+1)(\beta+2)}{1.2.3\gamma(\gamma+1)(\gamma+2)}x^3 + \dots$$

where x is the variable.

The term "hypergeometric series" appears in Euler's *Institutiones calculi integralis* [92] (1769), Chapter XI. The series is a solution of the so-called Euler hypergeometric differential equation which appears in Chapters VIII and XI of the same treatise. As a matter of fact, this name was given to several different but closely related objects. Euler, in one of his earliest memoir *De progressionibus transcendentibus seu quarum termini generales algebraice dari nequeunt* (On transcendental progressions, that is, those whose general terms cannot be given algebraically) [65], published in 1738, starts by mentioning Wallis's "hypergeometric series" $1! + 2! + 3! + 4! + \cdots$ (without the factorial notation). The terminology here refers to the fact that in analogy with the case of geometric progressions, where each term is obtained from the preceding one by multiplying it by a constant, one defined a hypergeometric progression as a progression in which each term is obtained from the preceding one by multiplying it by a factor which increases by a unit at each step. Wallis's papers on this subject include [251] (1, Scholium to Proposition 190) and [252] (p. 315).

Gauss mentions a hypergeometric series in his doctoral dissertation *Demonstratio nova theorematis omnem functionem algebraicam rationalem integram unius variabilis in factores reales primi vel secundi gradus resolvi posse* [119] (New proof of the theorem that every rational integral algebraic function of one variable can be resolved into real factors of the first or second degree) (1799).

We refer the reader to the paper [59] for a comprehensive history of the hypergeometric series.

At the beginning of his announcement of his memoir [222], Riemann states: "This memoir treats a class of functions which are useful to solve various problems in mathematical physics." As a matter of fact, these functions are still commonly used today in mathematical physics. Riemann notes that the name *hypergeometric series* was first proposed by Pfaff, for a more general series, whereas Euler, after Wallis, used such a name for a series which is slightly different. Pfaff was Gauss's friend, and had been his teacher. He studied this function in his book *Disquisitiones analyticae maxime ad calculum integralem et doctrinam serierum pertinentes* (Analytic investigations most relevant for integral calculus and the doctrine of series) [195] (1797). Gauss has a series of unpublished results on the hypergeometric series, which he communicated to the astronomer Bessel, who was also his friend, in a letter dated September 3, 1805. The results were used by Gauss in his later works. In his writings on the subject, Gauss used continued fractions in his study of the quotient of two hypergeometric series. He developed these ideas in his paper *Disquisitiones generales circa serium* $1 + \frac{\alpha\beta}{1.\gamma}x + \frac{\alpha(\alpha+1)\beta(\beta+1)}{1.2\gamma(\gamma+1)}xx + \frac{\alpha(\alpha+1)(\alpha+2)\beta(\beta+1)(\beta+2)}{1.2.3\gamma(\gamma+1)(\gamma+2)}x^3 + \ldots$ *etc.* (General investigations on the series $1 + \frac{\alpha\beta}{1.\gamma}x + \frac{\alpha(\alpha+1)\beta(\beta+1)}{1.2\gamma(\gamma+1)}xx + \frac{\alpha(\alpha+1)(\alpha+2)\beta(\beta+1)(\beta+2)}{1.2.3\gamma(\gamma+1)(\gamma+2)}x^3 + \ldots$ etc.) [122]. The same year, he wrote another paper on the same subject which he never published but which is contained in his *Collected Works* edition [123]. Riemann, in his paper [222], proved that these fractions converge in the complex plane cut along the subset $[2, +\infty]$ of the x-axis. In the same memoir, he introduced in the study of the hypergeometic functions a new method, which applies to all functions that satisfy linear differential equations with algebraic coefficients. He recalls in the announcement of that memoir, published in the *Göttinger Nachrichten*, No. 1, 1857, that Euler and Gauss made a thorough study of these functions from the theoretical point of view.

In the introduction to his paper [122] Gauss declares that practically any transcendental function that appears in analysis may be obtained as a special case of the hypergeometric series. In fact, it is known that functions like $\log(1 + z)$, $\arcsin z$ and several orthogonal polynomials, including Legendre polynomials and Chebyshev polynomials, can be expressed using hypergeometric functions. The so-called confluent hypergeometric function (or Kummer's function) is a limit of the hypergeometric function.

The introduction of the hypergeometric series brought a whole new class of new functions to the field of analysis which, at least in the times of Euler, consisted in the study of functions.

6 The Zeta Function

This section is concerned with Riemann's article *Über die Anzahl der Primzahlen unter einer gegebenen Grösse* (On the number of primes less than a given magnitude) [219]. This memoir, which is only 8 pages long, changed the course of mathematics. Riemann wrote it at the occasion of his election to the Berlin Academy of Sciences, on August 11, 1859. Every newly elected member at that academy was asked to report on his most recent research, and Riemann chose this topic. A short history of the subject will show that the list of predecessors of Riemann in this field includes names which are familiar to us now: Euler, as always, then Legendre, Dirichlet and Gauss.

Riemann starts his memoir by recalling that Gauss and Dirichlet had been interested in this subject several years before him. He displays the following formula, which he recalls was noted by Euler, and which was his own departure point:

O * /

> and even engines and motion in character, in the same way as algebra represents numbers in magnitude.[65]

In the same letter ([176] p. 570), Leibniz adds:

> I found the elements of a new characteristic, completely different from Algebra and which will have great advantages for the exact and natural mental representation, although without figures, of everything that depends on the imagination. Algebra is nothing but the characteristic of undetermined numbers or magnitudes. But it does not directly express the place, angles and motions, from which it follows that it is often difficult to reduce, in a computation, what is in a figure, and that it is even more difficult to find geometrical proofs and constructions which are enough practical even when the Algebraic calculus is all done.[66]

Together with his letter to Huygens, Leibniz included the manuscript of an essay he wrote on the new subject. He writes, in the same letter ([176] p. 571):

> But since I don't see that anybody else has ever had the same thought, which makes me fear that it might be lost if I do not get enough time to complete it, I will add here an essay which seems to me important, and which will suffice at least to rendre my aim more credible and easier to conceive, so that if something prevents its realization now, it will serve as a monument for posterity and give the possibility to somebody else to finish it.[67]

He then explains in more detail his vision of this new domain of mathematics, and where it stands with respect to algebra and geometry, giving several examples of a formalism to denote loci, showing how this formalism expresses statements such that the intersection of two spherical surfaces is a circle, and the intersection of two planes is a line.

Leibniz' letter ends with the words ([174] p. 25):

---

[65] Après tous les progrès que j'ai faits en ces matières, je ne suis pas encore content de l'Algèbre, en ce qu'elle ne donne ni les plus courtes voies, ni les plus belles constructions de Géométrie. C'est pourquoi lorsqu'il s'agit de cela, je crois qu'il nous faut encore une autre analyse proprement géométrique ou linéaire, qui nous exprime directement *situm*, comme l'algèbre exprime *magnitudinem*. Et je crois d'en avoir le moyen, et qu'on pourrait représenter des figures et même des machines et mouvements en caractères, comme l'algèbre représente les nombres en grandeurs. [We have modernized the French.].

[66] J'ai trouvé quelques éléments d'une nouvelle caractéristique, tout à fait différente de l'Algèbre, et qui aura de grands avantages pour représenter à l'esprit exactement et au naturel, quoique sans figures, tout ce qui dépend de l'imagination. L'Algèbre n'est autre chose que la caractéristique des nombres indéterminés ou des grandeurs. Mais elle n'exprime pas directement la situation, les angles et les mouvements, d'où vient qu'il est souvent difficile de réduire dans un calcul ce qui est dans la figure, et qu'il est encore plus difficile de trouver des démonstrations et des constructions géométriques assez commodes lors même que le calcul d'Algèbre est tout fait.

[67] Mais comme je ne remarque pas que quelqu'autre ait jamais eu la même pensée, ce qui me fait craindre qu'elle ne se perde, si je n'y ai pas le temps de l'achever, j'ajouterai ici un essai qui me paraît considérable, et qui suffira au moins à rendre mon dessein plus croyable et plus aisé à concevoir, afin que si quelque hasard en empêche la perfection à présent, ceci serve de monument à la postérité, et donne lieu à quelque autre d'en venir à bout.

> I have only one remark to add, namely, that I see that it is possible to extend the characteristic to things which are not subject to imagination. But this is too important and it would lead us too far for me to be able to explain myself on that in a few words.[68]

When Leibniz started his correspondence with Huygens, the latter was already a well established scientist whose achievements were behind him, and it was not easy to convince him of the usefulness of a new theory. Huygens thought that the theory was too abstract and he remained skeptical about it. He was above all a geometer working on concrete geometrical problems.

One may recall that when Leibniz sent him the above letter, Huygens was considered as a world authority in geometry and physics. He was settled in Paris since 15 years, and he was a leading member of the *Académie Royale des Sciences*. Leibniz had studied mathematics with Huygens, who was seventeen years older than him, and he considered him as his mentor. Huygens responded to Leibniz in a letter dated November 22, 1679 ([176] p. 577):

> I have examined carefully what you are asking me regarding your new characteristic, and to be frank with you, I cannot not conceive the fact that you have so much expectations from what you spread on me. Because your example of places concerns only realities which were already perfectly known, and the proposition saying that the intersection of a plane and a spherical surface makes the circumference of a circle does not follow clearly. Finally, I cannot see in what way you can apply your characteristic to which you seem you want to reduce all these different matters, like the quadratures, the invention of curves by the properties of tangents, the irrational roots of equations, Diophantus' problems, the shortest and the most beautiful constructions of the geometric problems. And what still appears to me stranger than anything else, the invention and the explanation of machines. I say it to you unsuspiciously, in my opinion this is only wishful thinking, and I need other proofs in order to believe that there could be some reality in what you present. I would nevertheless restrain myself from saying that you are mistaken, knowing the subtlety and the deepness of your mind. I only beg you that the magnificence of the things you are searching won't let you postpone from giving us those which you already found, like this Arithmetic Quadrature you discovered, concerning the roots of the equations beyond the cubical, if you are still satisfied with it.[69]

---

[68] Je n'ai qu'une remarque à ajouter, c'est que je vois qu'il est possible d'étendre la caractéristique jusqu'aux choses, qui ne sont pas sujettes à l'imagination ; mais cela est trop important et va trop loin pour que je me puisse expliquer là-dessus en peu de paroles.

[69] J'ai examiné attentivement ce que vous me demandez touchant votre nouvelle caractéristique, mais pour vous l'avouer franchement, je ne conçois pas parce que vous m'en étalez, que vous y puissiez fonder de si grandes espérances. Car votre exemple des Lieux ne regarde que des vérités qui nous étaient déjà fort connues, et la proposition de ce que l'intersection d'un plan et d'une surface sphérique fait la circonférence d'un cercle, s'y conclut assez obscurément. Enfin, je ne vois point de quel biais vous pourriez appliquer votre caractéristique à toutes ces choses différentes qu'il semble que vous y vouliez réduire, comme les quadratures, l'invention des courbes par la propriétés des tangentes, les racines irrationnelles des Équations, les problèmes de Diophante, les plus courtes et plus belles constructions des problèmes géométriques. Et ce qui me paraît encore le plus étrange, l'invention et l'explication des machines. Je vous le dis ingénument, ce ne sont là à mon avis que de beaux souhaits, et il me faudrait d'autres preuves pour croire qu'il y eût de la réalité dans ce que vous avancez. Je n'ai pourtant garde de dire que vous vous abusiez, connaissant d'ailleurs la subtilité et profondeur de votre esprit. Je vous prie seulement que la grandeur des choses que vous cherchez ne vous fasse point différer de nous donner celles que vous avez déjà trouvées, comme est

In another letter dated January 11, 1680 ([176] p. 584) Huygens writes:

> For what concerns the effects of your characteristic, I see that you insist on being persuaded of them, but as you say yourself, the examples will be more important than reasonings. This is why I am asking you much simpler examples, but capable of overcoming my incredulity, because that of the places, I confess, does not seem to me of that sort.[70]

The essay that Leibniz sent did not obtain Huygens' backing and it remained hidden among other manuscripts in Huygens' estate. It was published for the first time in 1833, and drew the attention of several nineteenth-century mathematicians, including Grassmann (1809–1877), the founder of the theory of vector spaces, who realized its importance for the new field of topology. There are two recent editions of this text, both included in doctoral dissertations, by J. Acheverría [175] (1995), in France, and by de Risi, [234] (2007), in Germany. The two dissertations contain other texts by Leibniz on the same subject.

Leibniz used several names for the new field, including *analysis situs, geometria situs, characteristica situs, characteristica geometrica, analysis geometrica, speciosa situs*, etc.

The first mathematician who worked consciously on topological questions is Euler. These questions include the definition and the invariance of the Euler characteristic of a convex polyheron, the problem known as that of the Königsberg seven bridges, another question related to the Knight's tour on the chessboard, and a musical question concerning a graph known as the *speculum musicum*. This graph was introduced in Euler's *Tentamen novae theoriae musicae ex certissimis harmoniae principiis dilucide expositae* (A attempt at a new theory of music, exposed in all clearness according to the most well-founded principles of harmony) [71]. Its vertices are the twelve notes of the chromatic scale, and the edges connect two elements which differ by a fifth or a major third with the property that one may traverse all the edges of the graph passing exactly once by each note. The article [189] is a detailed survey of the work of Euler on these questions. In the present section, we start by reviewing the work of Euler on the question of the seven bridges of Königsberg. This work shows that Euler considered himself as the direct heir of Leibniz for what concerns the field of topology. We shall then describe in detail the works of Euler and Descartes on the Euler characteristic, a question which is directly related to the topological classification of surfaces, which was one of Riemann's major achievements in topology. We recall that Euler formulated this result for a surface which is the boundary of a convex polyhedron having F faces, A edges and S vertices; the formula is then:

$$F - A + S = 2.$$

(Footnote 69 continued)
cette Quadrature Arithmétique et que vous avez découvert pour les racines des équations au-delà du cube, si vous en êtes content vous-même.

[70] Pour ce qui est des effets de votre caractéristique, je vois que vous persistez à en être persuadé, mais, comme vous dites vous-même, les exemples toucheront plus que les raisonnements. C'est pourquoi je vous en demande des plus simples, mais propres à convaincre mon incrédulité, car celui des lieux, je l'avoue, ne me paraît pas de cette sorte.

We start with the problem of the Königsberg bridges.

In the eighteenth century, the city of Königsberg[71] consisted of four quarters separated by branches of the river Pregel and related by seven bridges. The famous "problem of the seven bridges of Königsberg" asks for a path in that city that starts at a given point and returns to the same point after crossing once and only once each of the seven bridges. At the time of Euler, this was a popular question among the inhabitants of Königsberg.

Euler showed that such a path does not exist. He presented his solution to the Saint Petersburg Academy of Sciences on August 26, 1735, and in the same year he wrote a memoir on the solution of a more general problem entitled *Solutio problematis ad geometriam situs pertinentis* (Solution of a problem relative to the geometry of position) [74]. Euler learned about the problem from a letter, dated March 7, 1736, sent to him by Carl Leonhard Gottlieb Ehler, one of his friends who was the mayor of Danzig[72] and who had worked as an astronomer in Berlin. Euler solved the problem just after he received the letter. In a letter dated March 13, 1736, written to Giovanni Marioni, an Italian astronomer working at the court of Vienna, Euler declares that he became interested in this question because he realized that the problem could not be solved using geometry, algebra or combinatorics, and that therefore he wondered whether "it belonged to the 'geometry of position,' (*geometria situs*) which Leibniz has so much sought for." In the same letter, Euler announced to Marioni that after some thought, he found a proof which applies not only to that case, but to all similar problems.

In the introduction of his paper, Euler writes (translation from [29]):

> In addition to that branch of geometry which is concerned with magnitudes, and which has always received the greatest attention, there is another branch, previously almost unknown, which Leibniz first mentioned, calling it the geometry of position. This branch is concerned only with the determination of position and its properties; it does not involve measurements, nor calculations made with them. It has not yet been satisfactorily determined what kind of problems are relevant to this geometry of position, or what methods should be used in solving them. Hence, when a problem was recently mentioned, which seemed geometrical but was so constructed that it did not require the measurement of distances, nor did calculation help at all, I had no doubt that it was concerned with the geometry of position, especially as its solution involved only position, and no calculation was of any use. I have therefore decided to give here the method which I have found for solving this kind of problem, as an example of the geometry of position.

Euler's work on this problem is commented in several articles and books.

We now come to Euler's polyhedron formula, and we start with Descartes.

Long before Euler came out with his formula $F - A + S = 2$ relating the faces (F), edges (A) and vertices (S) of a convex polyhedron, Descartes obtained an equivalent result, with a geometric proof, involving the solid angles and the dihedral angles between the faces. Described in modern terms, Descartes' proof consists in computing in two different manners the total curvature of the boundary of the polyhedron.

---

[71] Today, the city of Königsberg, called Kaliningrad, is part of a Russian exclave between Poland and Lithuania on the Baltic Sea.

[72] Today, Danzig is the city of Gdansk, in Poland.

> the surface dependent on that of the various sections that one can perform on it by cutting it with planes.[89]

Meusnier's work is surveyed by Darboux in the paper [49].

Dupin is mostly known for the so-called Dupin indicatrix, a geometric device which characterizes the shape of a surface at a given point and which turned out to be related to the Gaussian curvature at that point. His famous work on geometry bears the title *Développements de géométrie, avec des applications à la stabilité des vaisseaux, aux déblais et remblais, au défilement, à l'optique, etc. pour faire suite à la géométrie descriptive et à la géométrie analytique de M. Monge : Théorie.* (Developments in geometry, with applications to the stability of vessels, cuts and fills, scrolling, optics, etc. as a sequel to the descriptive and analytic geometry of Mr. Monge: Theory) [58], 1813.

Rodrigues introduced, before Gauss, the Gauss map, and showed that at a given point the ratio of the area of the image to the area on the surface is equal (at the infinitesimal level) to the product of the two principal curvatures (those defined by Euler), cf. [235]. This result pre-dates that of Gauss, but the fact that curvature is an isometry invariant is however absent from Rodrigues' work.

Finally, it is fair to mention that Riemann's work in high dimensions was prepared by works of other mathematicians done in higher dimensions, and we mention in particular Jacobi [145] on the reduction of pairs of quadratic forms, Grassmann on higher-dimensional linear algebra [131], and Cayley [41] on higher-dimensional analytic geometry.

10 Trigonometric Series

Riemann's habilitation dissertation (*Habilitationsschrift*) is concerned with trigonometric series. Its title is *Über die Darstellbarkeit einer Function durch eine trigonometrische Reihe* (On the representability of a function by a trigonometric series) [215]. The dissertation is divided into two parts. The first part is a survey of the history of the problem of representing by a trigonometric series a function which is arbitrary, but which—according to Riemann's words at the beginning of his memoir—is "given graphically." It is important to note the last fact, since, for instance, a function which is discontinuous at a dense set of points cannot be given graphically. Dealing with the most general functions is part of the subject of the second part of Riemann's memoir.

We shall report on the historical part of Riemann's memoir. It involves several mathematicians, in particular Euler, although not directly his work on trigonometric series. We therefore note right away that Euler uses trigonometric series in his two

---

[89] M. Euler a traité la même matière dans un fort beau mémoire, imprimé en 1760 parmi ceux de l'Académie de Berlin. Cet illustre géomètre envisage la question d'une manière différente de celle que nous venons d'exposer ; il fait dépendre la courbure d'un élément de surface de celle des différentes sections qu'on peut y faire en le coupant par des plans.

We conclude with Grothendieck's reference to Riemann. In his *Sketch of a program*, [134], he writes (p. 240 of the English translation)[111]:

> Whereas in my research before 1970, my attention was systematically directed towards objects of maximal generality, in order to uncover a general language adequate for the world of algebraic geometry [...] here I was brought back, via objects so simple that a child learns them while playing, to the beginnings and origins of algebraic geometry, familiar to Riemann and his followers!

$$ds = \sqrt{\sum (dx)^2}.$$

Riemann noted that there are other possibilities. For example, ds could be the fourth root of a fourth power expression, but he did not see many possibilities for geometry there and he set this aside.

The quadratic form, however, did interest him. It contains $n(n+1)/2$ coefficients, of which n can be altered by a change of variables, so it depends essentially on $n(n-1)/2$ coefficients that are determined by the manifold. The example of $\sqrt{\sum (dx)^2}$ is therefore special, and Riemann proposed to call such manifolds flat.

To proceed further, Riemann considered the infinitesimal triangle with one vertex at the origin, one on a geodesic out of the origin to the point $(x_1, x_2, \ldots, x_n)$, and one on a geodesic out of the origin to the point $(dx_1, dx_2, \ldots, dx_n)$. The quotient of $\sqrt{\sum (dx)^2}$ by the area of this triangle measures the departure of this infinitesimal region from flatness, and divided by $-3/4$ is in fact the Gaussian curvature of the surface. So the curvature of an n-manifold can be understood by knowing $n(n-1)/2$ surface curvatures (the sectional curvatures, as we would say).

This led Riemann to explain the difference between intrinsic and extrinsic properties of a surface. He explained that for a sphere, which has an intrinsic geometry different from a plane, the Gaussian curvature multiplied by the area of an infinitesimal geodesic triangle is half the excess of the sum of its angles over π. This allowed him to express the belief that the geometry of an n-dimensional manifold could be understood by understanding its sectional curvatures.

Flat manifolds, he observed, have every sectional curvature zero. They are therefore a special case of the manifolds of constant curvature (that is, having the same sectional curvatures everywhere) and in these manifolds geometric figures can be freely moved around without stretching. To give examples of such manifolds he wrote down the metric

$$ds = \frac{1}{1 + \frac{\alpha}{4} \sum x^2} \sqrt{\sum (dx)^2},$$

where α is the curvature.

It was evident that the surfaces of constant positive curvature are spheres; the sphere of radius r has curvature r^{-2}. Riemann gave a complicated description of how to fit all the surfaces of constant curvature into one family. On this description, the cylinder is the example of a surface of zero curvature, and surfaces of constant negative curvature are locally like the saddle-shaped part of a torus.

In the third and final part of his paper [24] Riemann discussed how his ideas might apply to space. If all the sectional curvatures are zero, the space is Euclidean. But if we assume only that there is free mobility of bodies then space is described as a three-dimensional manifold of constant curvature, which can be determined from the knowledge of the sum of the angles in any triangle. Or, one could assume that length is independent of position but not direction.

Riemann's Work on Minimal Surfaces

Sumio Yamada

Abstract Three months before his death in 1866, Riemann left a set of notes to K. Hattendorff, a disciple of his, on minimal surfaces with boundary. Afterwards, Hattendorff supplied the text to the notes mostly consisting of computations, which became the two papers on the subject: "On the surface of least area with a given boundary" and "Examples of surfaces of least area with a given boundary." We will go over the expositions and provide an overview from the modern viewpoint, make some comments on Riemann-Hattendorff's text, and compare the work with that of Weierstrass on the same subject.

Keywords Riemann · Minimal surface · Calculus of variations

1 Introduction

We first recall the statement of the Riemann mapping theorem,

Theorem 1.1 *If* Ω *is a non-empty simply connected open proper subset of the complex plane* $\mathbb{C}$*, then there exists a bi-holomorphic mapping* f *from* Ω *onto the open unit disk* $D = \{z \in \mathbb{C} \mid |z| < 1\}$.

We remark that the resulting plane region Ω is a minimal surface spanned by the boundary $\partial\Omega$ when the complex plane is identified with the xy-plane in the three dimensional ambient space $\mathbb{R}^3$.

It was in Riemann's thesis [8] in 1851 where the cerebrated Riemann Mapping Theorem was first presented. There he utilized the Dirichlet principle in order to obtain a map which is harmonic and conformal from a simply connected region of the complex plane to the unit disc. Riemann's proof was incomplete as the existence of such harmonic functions minimizing the Dirichlet energy functional is not always

guaranteed, a defect first pointed out by Weierstrass in 1859. The subsequent important historical development in analysis and geometry initiated by Riemann's idea of using the Dirichlet principle, which led to the wealth of mathematics around the so-called Plateau problem, is comprehensively described in Courant's book [2].

Hans Lewy, in his introduction [5] to an edition of collected works of Riemann (1953), speculates that the work of Riemann on the subject of minimal surfaces in $\mathbb{R}^3$ [9, 10] may well be an attempt to rectify his own proof of the Riemann Mapping Theorem, as the inverse map $f^{-1} : D \to \Omega \subset \mathbb{R}^3$ of the Riemann mapping provides a harmonic and conformal parameterization of the *minimal* surface $\Omega \subset xy$-plane, where the xy-plane is identified as $\mathbb{C}$. The set of minimal surfaces Riemann succeeded in constructing, however, have boundary sets only of special types; lines, line segments, circles, with which one would not be able to approximate an arbitrary boundary curve $\partial\Omega$ as required by the statement of the Riemann Mapping Theorem.

Having stated this observation about a failed attempt, however, it is important to recognize the true value of what Riemann created in the field of minimal surfaces within the two posthumously published papers [9, 10]. Historically, the study of minimal surfaces and later minimal submanifolds has led to many interesting applications, not only in differential geometry, but also in general relativity, material sciences, industrial design, among others. Riemann was correct to foresee the scientific potential the subject offered. As for the minimal surfaces in $\mathbb{R}^3$, much of the subsequent development on the subject up to the present day is based on the so-called Weierstrass-Enneper representation formula, which is comprehensively presented in [11].

The goal of this chapter is to illustrate that inside the notes Riemann left to Hattendorff, based on the computations Riemann had made over 1860–61, much of the well-known classical results on minimal surfaces including the Weierstrass-Enneper representation, Schwarz's explicit construction of minimal surfaces, as well as the Schwarz-Christoffel transformation, are contained in essence. We will demonstrate this by reading the text of [9] through §1–13 with comments added as appropriate. In particular in the second to the last section, we provide a direct comparison between the Weierstrass-Enneper representation and the much less known Riemann representation of minimal surface.

2 On the Surface of Least Area with a Given Boundary

Regarding the treatment of surfaces in $\mathbb{R}^3$ in this article, it is safe to assume that Riemann was fully informed of the surface theory of Gauss [4] where every surface is locally parameterized by two independent real variables u, v.

In §1 and §2, a disc-type surface Ω is parameterized by two parameters p, q which are effectively the polar coordinates in the two-dimensional disc D_r; $p \in [0, r]$ on the radial set $\{q = \text{const.}\}$ and $q \in [0, 2\pi\rho)$ on the circle $\{p = \rho\}$. Then a

;. 8 5 AA6

in his paper [91], also formulated problems concerning the projection of subsets of the sphere onto the Euclidean plane in terms of partial differential equations. Likewise, Lagrange used the notion of conformal map in his papers on cartography [88], and the same notion is inherent in Gauss's work. The terminology "isothermal coordinates" which the latter introduced, referring to a locally conformal map between a subdomain of the plane and a subdomain of the surface, indicates the relation with physics. Riemann, in his dissertation, refers to an 1822 paper by Gauss, published in the *Astronomische Abhandlungen* in 1825 (but written several years before).[24] The title of that paper is *Allgemeine Auflösung der Aufgabe: die Theile einer gegebnen Fläche auf einer andern gegebnen Fläche so abzubilden, daß die Abbildung dem Abgebildeten in den kleinsten Theilen ähnlich wird* (General solution of the problem: to represent the parts of a given surface on another so that the smallest parts of the representation shall be similar to the corresponding parts of the surface represented), a paper presented to a prize question proposed by the Royal Society of Sciences at Copenhagen, [61]. In this paper, Gauss shows that every sufficiently small neighborhood of a point in an arbitrary real-analytic surface can be mapped conformally onto a subset of the plane.[25]

After recalling the definition of a conformal map, Riemann passes to the equivalent condition expressed in terms of partial differential equations. Here, we are given a function f of a complex variable which is composed of two functions u and v of two real variables x and y:

$$f(x + iy) = u + iv.$$

The functions u and v are differentiable and satisfy the Cauchy–Riemann equations. They appear as *potentials* in the space of the two variables x and y. Klein, in his article on *Riemann and his significance for the development of modern mathematics* writes ([86] p. 168):

> Riemann's method can be briefly characterized by saying that *he applies to these parts u and v the principles of the theory of the potential*. In other words, his starting point lies in the domain of mathematical physics.

In the same article (p. 170), after explaining some of Riemann's tools, Klein adds:

> All these new tools and methods, created by Riemann for the purpose of pure mathematics out of the physical intuition, have again proved of the greatest value for mathematical physics. Thus, for instance, we now always make use of Riemann's methods in treating the *stationary* flow of a fluid within a two-dimensional region. A whole series of most interesting problems, formerly regarded as insolvable, had thus been solved completely. One of the best known problems of this kind is Helmholtz's determination of the shape of a free liquid jet.

---

[24] The paper won a prize for a question proposed by the Copenhagen Royal Society of Sciences in 1822. The subject of the competition was: "To represent the parts of a given surface onto another surface in such a way that the representation is similar to the original in its infinitesimal parts." A letter from Gauss to Schumacher dated July 5, 1816 shows that the solution was already known to Gauss at that time; cf. Gauss's *Werke* Vol. 8, p. 371.

[25] Gauss did not solve the problem of mapping conformally an arbitrary finite portion of the surface; this was one of the questions considered by Riemann. An English translation of Gauss's paper is published in [153], Volume 3.

the Habilitationsvortrag in 1919, [164], together with a commentary, making the link with relativity theory. One of the main features of the local geometry conceived by Riemann is that it is well suited to the study of gravity and more general fields in physics. Relativity theory, which encompasses the largest part of modern physics, relies in a crucial way on the notions introduced by Riemann.

From the purely mathematical point of view, the most important contribution of the Habilitationsvortrag is that it sets the bases of what we call today Riemannian geometry, with the introduction of the curvature tensor and its consequences, including several results such as the fact that the homogeneity (with the inherent notion of transformation group) corresponds to constant curvature. This new geometry can be considered as a far-reaching generalization of Gauss's work on the intrinsic geometry of surfaces, and at the same time it is a generalization of the non-Euclidean geometry (of constant curvature) discovered by Lobachevsky, Bolyai and Gauss, in the few decades that preceded Riemann. Furthermore, Riemann sets in this memoir the bases of several developments made in several directions by Clifford, Christoffel, Bianchi, Ricci, Beltrami, Levi-Civita, Élie Cartan, Einstein and many others.

It is known that the full importance of the Habilitationsvortrag was not recognized in the first years after it was delivered. A report by Dedekind on the mathematical content of the memoir was published only in 1868.[44] But it is also known that Gauss, who, as Riemann's mentor, was present at the lecture, expressed his complete satisfaction with it. This reaction to Riemann's Habilitationsvortrag is described in Dedekind's biography of Riemann published in the Collected Works [141]. Gauss's praise was certainly a cause for Riemann's own contentedness, because Gauss was known to be sparing with compliments.

In the introduction to his dissertation, Riemann declares that he is unexperienced in philosophical questions, and that in preparing the lecture he could rely only on some remarks that Gauss made in his second paper on biquadratic residues and in his Jubilee-book, and some philosophical researches of Herbart. Riemann discusses the question of space and that of manifoldness and its specialization. This specialization may be either continuous or discrete. In the chapter [119] contained in the present volume, Plotnitsly emphasizes that Riemann speaks of discrete manifolds, and then says that, rather than space itself, it is "the reality underlying space" that may be discrete.[45] "Manifolds" as we intend them today are particular cases of manifoldnesses. Riemann writes:

> Manifoldnesses in which, as in the plane and in space, the line-element may be reduced to the form $\sqrt{\sum dx^2}$, are therefore only a particular case of the manifoldnesses to be here investigated; they require a special name, and therefore these manifoldnesses in which the square of the line-element may be expressed as the sum of the squares of complete differentials I will call *flat*.

---

[44] *Abhandlungen der Königlichen Gesellschaft der Wissenschaften zu Göttingen, 13.*

[45] It may be useful to note that in modern physics, spacetime is studied in its both characters, discrete (e.g., in lattice gauge theories, which are often considered as mathematical discrete approximations) or as continuous (e.g., in general relativity).

Riemann declares that notions whose specializations form a continuous manifoldness are the positions of perceived objects (die Orte der Sinnengegenstände) and colors. It is conceivable that Riemann, in his mention of colors, refers to the fact that one can continuously move from a color to another one, a color being characterized by the proportions of red, green and violet it contains. This makes color a three-dimensional manifoldness. Weyl writes, in his *Space, time, matter*, that Riemann's reference to color "is confirmed by Maxwell's familiar construction of the color triangle" ([165], p. 84 of the English translation). There are also writings of Helmholtz and Thomas Young on this matter. There are particular portions of a manifoldness called *quanta*,[46] whose nature is different from that which is characterized by the discrete and the continuous. "Their comparison with regard to quantity is accomplished in the case of discrete magnitudes by counting, in the case of continuous by measuring." The notions of measurement and of dimension are discussed in the Aristotelean style. The relation between measurement and the axioms of geometry is said to be fundamental, and in some sense this question concerns the relation between the axioms of geometry and the reality of space, that is, between mathematical and empirical truth. Riemann writes:

> Either therefore the reality which underlies space must form a discrete manifoldness, or we must seek the ground of its metric relations outside it, in binding forces which act upon it.[47]

It is important to recall Riemann's words. He declares that geometry depends at the same time on axioms and on observational and experimental physics. He considers that classical geometry, with the first principles and axioms that it assumes and the connections between them, does not lead anywhere, because "we do not perceive the necessity of these connections." What is missing is a notion of "multiply-extended magnitude" (mehrfach ausgedehnte Grösse), a notion which makes space a particular "triply-extended magnitude." He proposes that the properties that distinguish space from other conceivable triply-extended magnitudes be deduced from experience. In particular, the space that Riemann talks about, although built from undefined notions and axioms connecting them, is not the space of traditional geometry. He suggests that this space should reflect the material world around us. He formulates the problem of finding the "simplest matters of fact from which the metric relations (Massverhältnisse) of space may be determined." He declares that these matters of fact are "not of necessity, but only of empirical certainty." They are the "hypotheses" that are referred to in the title of the dissertation. He says that he will investigate the "probability" of these matters of fact, "within the limits of observation," and see whether they may be extended "beyond the limits of observation, both on the side of the infinitely great and of the infinitely small." The most important among these matters of fact is related to the work of Euclid. The geometry that Riemann will

---

[46] In Aristotle's language, the latin word *quantum* is used as the translation of the word *ποσόν* (quantity, or "quantified thing"), which is one of Aristotle's categories. In his *Metaphysics*, Aristotle mentions four types of change: of substance, *quale*, *quantum*, or place. (Metaphysics, 1069b9–13).

[47] Es muss also entweder das dem Raume zu Grunde liegende Wirkliche eine discrete Mannigfaltigkeit bilden, oder der Grund der Massverhältnisse ausserhalb, in darauf wirkenden bindenden Kräften, gesucht werden.

construct will be Euclidean at the infinitesimal level.[48] We already noted by the way that the notion of "infinitely small" is treated in several works of the Ancient Greeks. The same notion is thoroughly discussed by Galileo Galilei in his *Discorsi; First day*, to whom Riemann refers in his habilitation, though in a different context.

The rest of the Habilitationsvortrag is a development of the ideas expressed in the introduction. The first part concerns the notion of n-dimensional Mannigfaltigkeit. This term is sometimes translated into English by "manifoldness." Riemann also talks about a "multiply extended magnitude." This is an ancestor to the mathematical notion of manifold. But the meaning of Mannigfaltigkeit, in Riemann's terminology, and that of the mathematical notion of manifold, as it is used today, do not coincide, even though in German the word Mannigfaltigkeit is used for "manifold."[49] There are discrete and continuous manifoldnesses, and there are manifoldnesses which are not mathematical. Riemann says that notions with specializations to discrete manifoldness are very common, but that, by contrast, there are very few notions whose specialization form a continuous manifoldness. We note incidentally that Poincaré pondered this terminology. In a letter to the mathematician and historian of mathematics Gustav Eneström, dated November 19, 1883 (cf. [120] p. 143), he writes:

> I prefer the translation of *Mannigfaltigkeit* by multiplicity, because the two words have the same etymological meaning. The word set is more adapted to the *Mannigfaltigkeiten* considered by Mr. Cantor and which are discrete. It would be less adapted to those which I consider and which are discontinuous. What is the opinion of Mr. Mittag on this matter?[50]

Eneström responds, on November 23:

> Mr. Mittag-Leffler thinks that you may be right, and, consequently, one should prefer the word multiplicity.[51]

In fact, Poincaré used the word multiplicity in its French form ("multiplicité") to denote Riemann's moduli space.

In the treatise *Théorie des fonctions algébriques de deux variables indépendantes* (Theory of algebraic functions of two independent variables) by Picard and Simart

---

[48] It may be worth recalling that Lobachevsky, in his various works on non-Euclidean geometry that he started in the late 1820s, systematically checked that the formulae that obtained in his new geometry give, at the infinitesimal level, the Euclidean formulae. See e.g. [93] p. 31.

[49] Jost, in [147], tries to sort out this complex terminology. He writes on p. 29: "The English of Clifford may appear somewhat old-fashioned for a modern reader. For instance, he writes 'manifoldness' instead of the simpler modern translation 'manifold' of Riemann's term 'Mannigfaltigkeit.' But Riemann's German sounds likewise somewhat old-fashioned, and for that matter, 'manifoldness' is the more accurate translation of Riemann's term. In any case, for historical reasons, I have selected that translation here."

[50] Je préfère la traduction de *Mannigfaltigkeit* par multiplicité, car les deux mots ont même sens étymologique. Le mot ensemble convient bien aux *Mannigfaltigkeiten* envisagés par M. Cantor et qui sont discrètes; il conviendrait moins à celles que je considère et qui sont discontinues. Qu'en pense M. Mittag à ce sujet?

[51] M. Mittag-Leffler pense que vous pouvez avoir raison, et que, par conséquent, il faut préférer le mot multiplicité.

Appel-Goursat-Fatou

Riemann surfaces are also thoroughly studied in the first volume of the treatise *Théorie des fonctions algébriques et de leurs intégrales et des transcendantes qui s'y rattachent* (Theory of algebraic functions and their integrals, and their related transcendentals) [6] by Appell, Goursat and Fatou, which appeared in 1929. In reality, the treatise is a revised edition, by Fatou, of the treatise [4] by Appell and Goursat. Fatou was at the same time a mathematician and an astronomer. In 1906, he defended a thesis entitled *Séries trigonométriques et séries de Taylor* (Trigonometric series and Taylor series), [29, 30], whose subject is Lebesgue's integration theory, which in some sense is a refinement of Riemann's integration theory (see Sect. 5 below). It is in this thesis that we find the famous Fatou Lemma (also called the Fatou-Lebesgue Lemma) on the comparison between the integral of a lower limit of positive measurable functions and the lower limit of their integrals. The lemma is a key element in the proof of the Dominated Convergence Theorem. In the same year, Fatou started his work on the iteration of rational maps of the plane, a work that was revived in the last two decades of the twentieth century by Sullivan, Thurston and others. Fatou also worked on the dynamics of transcendental functions.

The title of the first volume of the treatise by Appell, Goursat and Fatou is *Étude des fonctions analytiques sur une surface de Riemann* (Study of analytic functions on a Riemann surface) [6]. In that treatise, Riemann surfaces are still represented, like in the 19th-century treatises, in an anthropomorphic fashion, (using Weyl's expression; see Sect. 2 of the present article). Figure 4 is extracted from that volume, and is already contained in the first edition by Appell and Goursat (Fig. 1 in Sect. 2 above). The authors declare, concerning the surface considered: "This surface is analogous to that represented in Fig. 10, with the difference that, in reality, the two leaves are infinitely close and the apertures are infinitely narrow.

Chapter III of this volume is entitled *Connexion des surfaces à deux feuillets. Périodicité des intégrales hyperelliptiques* (Connectivity of two-sheeted surfaces and periodicity of hyperelliptic integrals). The authors start by saying (p. 99):

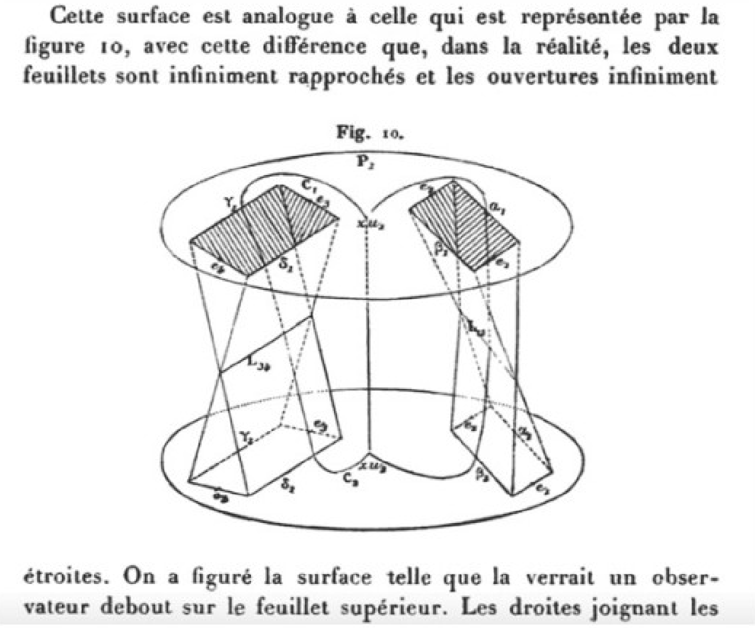
> In what follows, we consider surfaces as leaves without thickness, in such a way that a point or a line drawn on that surface will be visible for a observer situated on one side or the other. These surfaces will be considered as *perfectly elastic and rip-stop*.[28]

Halphen

Among the other treatises that are related to Riemann surfaces, we mention Halphen's *Traité des fonctions elliptiques et de leurs applications* (A treatise on elliptic fonctions and their applications) in 3 volumes, published in 1886, 1888 and 1891 [41].

---

[28] Dans ce qui suit, nous considérons des surfaces comme des feuillets sans épaisseur, de sorte qu'un point ou une ligne tracée sur la surface seront visibles pour un observateur placé d'un côté ou de l'autre. Les surfaces seront en outre regardées comme *parfaitement élastiques et indéchirables*.



Cette surface est analogue à celle qui est représentée par la figure 10, avec cette différence que, dans la réalité, les deux feuillets sont infiniment rapprochés et les ouvertures infiniment

Fig. 4 A picture from the treatise by Appell, Goursat and Fatou [6]. One can read in the text above the figure: "This surface is analogous to the one presented in Fig. 10, with the difference that, in reality, the two sheets are infinitely close, etc.," and, below the figure: "We have represented the surface in the way an observer standing on the upper sheet would see it."

This treatise had a certain impact on students in algebra and analysis. Georges-Henri Halphen, was a graduate of the École Polytechnique,[29] and he started with a career in the army. He submitted a doctoral dissertation on 1878, titled *Sur les invariants différentiels* (On differential invariants) [40], in which he determined the invariants of planar or skew curves under projective transformations. His thesis committee consisted of Hermite, Bouquet and Darboux. Haplhen participated to the 1870 French-German war. In 1872, he was appointed *répétiteur*[30] at the École Polytechnique. He was a specialist, among other things, of differential invariants, elimination theory, and singularities of algebraic curves. Picard, in biography of Halphen [82], writes the following (p. x of the Introduction):

> Riemann, in his theory of Abelian functions, had introduced the major notion of genus of elliptic curves, and he classified them into different classes, two curves being in the same class whenever there is a uniform correspondence between them. The famous geometer, who liked the great horizons, passed quickly on more than one difficult point, in particular, for what concerns higher singularities. Halphen gave a general formula, which applies to all cases, for the determination of the genus of an algebraic curve. Then, passing to the study of curves belonging to the same class, he went deeper into a remarkable proposition of

---

[29] We remind the reader that the École Polytechnique is a military school.

[30] A kind of a teaching assistant.

> Mr. Nœther according to which one may find in every class curves that have only ordinary singularities [...][31]

The first part of Halphen's treatise concerns the general theory of elliptic functions. The second part makes this treatise special compared to the other treatises on the same subject: it concerns the applications of elliptic functions to various branches of mathematics and physics. The subtitle of that volume is *Applications à la mécanique, à la physique, à la géodésie, à la géométrie et au calcul intégral* (Applications to mechanics, physics, geodesy, geometry and integral calculus). It was known since the eighteenth century, that is, since the birth of the theory of elliptic functions, that these functions have many applications in physics. It suffices to recall in this respect that these functions are in some sense generalizations of the familiar trigonometric functions, and that they can be used to represent a large class of periodic phenomena. For instance, whereas the small oscillations of a pendulum are represented by the sine functions (which is the inverse function of the elliptic integral $\int_0^x \frac{dt}{\sqrt{1-t^2}}$), for large oscillations, one needs (inverses of) more general elliptic integrals. By the time of Riemann, elliptic integrals were used in problems of gravitation and electromagnetism. We recall in this respect that the famous treatise of Legendre, *Exercices de calcul intégral* (Exercises of integral calculus) [63] contains a substantial part on elliptic integrals and their applications to problems in geometry and mechanics. We also note that the subtitle of the first volume of Legendre's *Traité des fonctions elliptiques et des intégrales eulériennes* (Treatise on elliptic functions and Eulerian integrals) [64] is: *Contenant la théorie des fonctions elliptiques et son application à différents problèmes de géométrie et de mécanique* (Containing the theory of elliptic functions and its application to various problems of geometry and mechanics). One may also mention in this respect that expressions of the lengths of arcs of an ellipse (which are precisely given by elliptic integrals) are obviously useful in celestial mechanics, since Kepler's first law says that orbits of planets in the solar system are ellipses with the Sun at one of their two foci. His second law says that a segment joining a planet and the Sun sweeps out equal areas during equal intervals of time. We also recall that Gauss was also an astronomer, and his interest in elliptic functions was motivated by his work on the trajectories of planets. Finally, Abel's 1827 famous paper on elliptic functions that we already mentioned, starts by mentioning the "beautiful properties" of Abelian functions "and their applications." He writes ([1] p. 101):

> Since a long time, the logarithmic functions, and the exponential and circular functions were the only transcendental functions that attracted the attention of the geometers. It is only in

---

[31] Riemann, dans sa théorie des fonctions abéliennes, avait introduit la notion capitale du genre des courbes algébriques, et partagé celles-ci en différentes classes, deux courbes étant de la même classe quand elles se correspondent uniformément. L'illustre géomètre, qui aimait les grands horizons, avait peu insisté sur plus d'un point difficile, en particulier sur ce qui concerne les singularités élevées. Halphen donne une formule générale, applicable à tous les cas, pour la détermination du genre d'une courbe algébrique; puis, passant à l'étude des courbes d'une même classe, il approfondit une proposition remarquable donnée par M. Noether, d'après laquelle on peut trouver dans toute classe des courbes n'ayant que des singularités ordinaires [...].

> recent times that some other functions started to be considered. Among them one has to distinguish the so-called elliptic functions, at the same time because of their beauty and of their use in the various branches of mathematics."[32]

The applications to geodesy mentioned by Halphen concern the geodesics on an ellipsoid of revolution whose ratio of major to minor axis is close to 1. Such a body is a representation of the shape of the Earth. It is also well known that Gauss was highly interested in geodesy. The applications of elliptic functions to geodesy were also considered by Jacobi in his paper [53]. In that paper, Jacobi solves a problem in geodesy which was addressed by Gauss. More details on elliptic functions are given in Chap. 1 of the present volume [76].

The third volume of Halphen's treatise contains fragments on elliptic functions which were collected after Halphen's death and published by Stieltjes.[33] The volume also contains Picard's biography of Halphen [82] which we already quoted. Picard declares there that Halphen was "one of the most eminent geometers in Europe."

Tannery and Molk

We now review the 4-volume treatise *Éléments de la théorie des fonctions elliptiques* (Elements of the theory of elliptic functions) [107] by Tannery and Molk. A few words on the authors are in order.

Jules Tannery (1848–1910) was a geometer, philosopher and writer. He edited the correspondence between Lagrange and d'Alembert.

In 1874, Tannery defended a doctoral dissertation whose title is *Propriétés des intégrales des équations différentielles linéaires à coefficients variables* (Properties of the integrals of linear differential equations with variable coefficients) [105] and [106]. The thesis committee consisted of Hermite, Briot and Bouquet. The dissertation starts with the following:

> The study of functions of an imaginary variable defined by an equation, a study which was substituted to the research, often unworkable, of the explicit form of these functions, profoundly renewed analysis in this century. It is well known that the glory of having shown this new way goes to Cauchy. The works of Mr. Puiseux on the solutions of algebraic equations, those of Messrs. Briot and Bouquet on doubly periodic functions and on differential equations, have largely proved the fertility of the idea of Cauchy in France. In Germany, the

---

[32] Depuis longtemps les fonctions logarithmiques, et les fonctions exponentielles et circulaires ont été les seules fonctions transcendantes qui ont attiré l'attention des géomètres. Ce n'est que dans les derniers temps qu'on a commencé à en considérer quelques autres. Parmi celles-ci il faut distinguer les fonctions, nommées elliptiques, tant pour leurs belles propriétés analytiques que pour leur application dans les diverses branches des mathématiques.

[33] Thomas Johannes Stieltjes (1856–1894) was Dutch but he decided to live in France. He acquired the French citizenship and in 1886 he became professor at the Faculté des Sciences de Toulouse. Stieltjes is known for several works on analysis and number theory, in particular on the so-called Stieltjes integral, elliptic functions, Dirichlet series, and is considered as the founder of the analytic theory of continued fractions. Stieltjes is also remembered for a failed attempt to prove the Riemann hypothesis, which he announced in his paper [104].

Planes of reference give rise to these formations, which define the disciplinary nature of mathematics and science, and essentially shape mathematical and scientific thinking and practice—essentially, but, I would argue, not completely or even most centrally, at least in creative mathematics and science. One might say that creative or, to adopt Thomas Kuhn's language, revolutionary, thought in philosophy and mathematics or science alike is defined by planes of immanence and creation of concepts in Deleuze and Guattari's sense, which always carry individual signatures underneath them [8, p. 50]. Just as there are Plato's ideas, Descartes's cogito, and Leibniz's monads, there are Gauss's curvature, Riemann's manifolds, Dedekind's ideals, and Grothendieck's topoi in mathematics, or Einstein's spaces curved by gravity in general relativity and Heisenberg's matrix variables or Dirac's spinors in quantum physics. This is true even though the functioning of mathematical and scientific concepts does require planes of reference, functions (or other formal mathematical entities), propositions, and so forth.

The difference between philosophy and mathematics or science may instead be, to stay with Kuhn's idiom, in the nature of *normal*, rather than *revolutionary*, practice in each domain. In philosophy, the normal practice consists primarily in understanding, interpreting, and commenting on concepts, while in mathematics and science, the normal practice consists primarily in creating, by means of planes of references, frames of reference, functions and other mathematical or scientific formations, propositions, and so forth. It is true that for Deleuze and Guattari creative, revolutionary philosophical practice is the only true philosophy. However, leaving aside an arguably too restrictive character of this view of philosophy, this is not in conflict with the view of creative mathematics or science advocated here.

Deleuze and Guattari do allow that creative mathematical and scientific thought, such as that of Riemann (one of their primary examples), could have philosophical or artistic, compositional, aspects. But they appear to associate these aspects with *philosophical* or, in Deleuze's language, *inexact* (but philosophically rigorous) thought within mathematical or scientific thought. This philosophical thought is either operative alongside mathematical and scientific thought or enters by way of interference (in the positive sense of interfering wave fronts rather than in the more negative sense of inhibition) between mathematics and philosophy [8, pp. 217–218]. Both types of association are pertinent and important, certainly in Riemann's case. My argument is different, however. I argue that creative *technical*, *exact* mathematical and scientific thought is defined by planes of immanence and multi-component mathematical or scientific concepts, the architecture of which is analogous to that of philosophical concepts in Deleuze and Guattari's sense. That is, even apart from their philosophical strata, *mathematical* and *scientific* planes of immanence and the nature of mathematical or scientific concepts are *analogous* to philosophical thought. It is not only a matter of mathematical and scientific thought becoming philosophical at certain junctures, but a matter of the mathematical and philosophical thought creating parallel homomorphic (partially corresponding to each other), although not isomorphic (fully corresponding to each other), architectures of mathematical and philosophical concepts. They are not isomorphic because of technical, exact, aspects of

T * * * = 3 * 0 " * = . 0 * 3 S 7 4= *3 0 * +* =

mathematical and scientific concepts, demanded by the disciplinary nature of mathematics and science, aspects, generally, not found in philosophical concepts.

To bring this point home, I need to say more about Deleuze and Guattari's conceptions of planes of immanence and reference. The plane of immanence, as the plane of the movement of thought, is not "a concept that is or can be thought," but is "the image of thought, the image that thought gives itself of what it means to think" [8, p. 37]. As they say: "Concepts are like multiple waves, rising and falling, but the plane of immanence is the single wave that roles them up and unrolls them" [8, p. 36]. The present argument aims to extend, rather than to juxtapose, the plane of immanence (and the relationship between it and concepts) to mathematical and scientific thought, and to join this plane with the plane of reference. For Deleuze and Guattari, mathematics or science "relinquishes the infinite, infinite speed [of thought], in order to a gain *a reference able to actualize the virtual* [of chaos]. [It] gives reference to the virtual, a reference that actualizes the virtual through functions [or other mathematical objects]" [8, p. 118; translation modified]. Thought's enactment of this process constitutes a plane of reference. Planes of reference do play a major, indeed irreducible, role in mathematical and scientific thinking, especially in the disciplinary functioning of mathematics and science. This, however, is not inconsistent with the view that planes of immanence and the creation of concepts are found in mathematics and science. Mathematical and scientific thought combines both planes (sometimes, as does philosophy, also adding planes of composition) and creates its concepts from this fusion. The processes of thought defined the plane of immanence and specifically the creation of concepts (in Deleuze and Guattari's sense) are equally found in mathematics and science, and, again, define creative thinking there most essentially, analogously to the way it happens in philosophy. Such mathematical planes of immanence and the concepts they give rise to may coexist and interact with philosophical planes of immanence and concepts, but they are not reducible to philosophical planes and concepts. This is because of the equally irreducible interaction between these mathematical planes and concepts with technical, exact aspects of mathematical and scientific thinking.

Thus, in his rethinking of spatiality and geometry, Riemann, not only laid out a philosophical plane of immanence that gives rise to philosophical concepts and architectures, as Deleuze and Guattari rightly argue [7, pp. 483–486] but also introduced *a new mathematical plane of immanence*, which gives rise to multicomponent mathematical concepts, alongside *a mathematical plane of reference*. Riemann's thought shaped the plane of immanence of modern mathematical thought arguably more than that of any other mathematician (although Newton, Gauss, and Galois before Riemann, and Poincaré and Hilbert after him offer some competition). This plane extends well beyond geometry. Riemann made major transformative contributions, especially of a conceptual nature, to many areas of modern mathematics: geometry, topology, analysis, algebra, and number theory–not the least by bringing these fields to bear on each other, and his contributions to physics or philosophy were part of this interactive thinking and practice.

The interactive heterogeneity of Riemann's practice is a crucial aspect of Riemann's mathematics, and it extends beyond mathematics and shapes its mathematical operation from this exterior. Thus, the plane of immanence of Riemann's thought also has a more strictly philosophical dimension and thus creates more strictly philosophical concepts, emphasized by Deleuze and Guattari, rather than only mathematical concepts analogous to philosophical concepts by virtue of their multi-component architecture, stressed here. Riemann's philosophical thought was uncommonly and even nearly uniquely significant for his mathematical or physical thought, although one could think of a few competing cases, such as Weyl, who might have been inspired by Riemann in this respect as well, as he was by many other aspects of Riemann's thought. So were the physical dimensions of Riemann's thought, and this, too, is shared by Weyl, or, earlier Gauss, although this is more common. This role of physics in their work is also essentially connected to the role of philosophy there, which is, again, uncommon, if one speaks of such essential connections, making one's philosophical thinking a constitutive part of one's mathematical thinking, rather than of general philosophical reflections concerning mathematics and science, on the part of mathematicians and scientists.[8] The creation of new mathematics in Riemann was enabled by all three dimensions—mathematical, physical, and philosophical—of Riemann's thought and concepts. Riemann lays out a new plane of immanence of mathematical thought by changing both how to think about geometry or space and how to pursue thinking differently mathematically, via bringing together different mathematical fields and combining them with physical and philosophical concepts. A similar claim could also be made about his thinking concerning physics.

Riemann's Habilitation lecture is a magnificent unfolding of this plane (a geometrical metaphor of "plane" is fitting here). It is a major contribution not only to mathematics but also to physics and philosophy, especially to the philosophy of mathematics and physics, but far from exclusively so, as, for example, Deleuze and Guattari's use of Riemann's concepts shows. It is difficult to overestimate the significance and impact of Riemann's thinking concerning spatiality and geometry in mathematics and physics, in shaping the planes of immanence of thought of both. In mathematics the list of even major areas of impact is nearly inexhaustible, and I shall only mention a few of, arguably, the most important ones. First of all, Riemann's rethinking of geometry in terms of manifoldness crucially expanded the idea of the multiplicity of spaces and geometries themselves. Riemann's view of geometry as, in Deleuze and Guattari's language, topology and typology of manifolds led from the late-nineteenth century on to the extraordinary (a still ongoing) progress of geometry, beginning with the work of Sophus Lie and Felix Klein, and a bit later Élie Cartan [7, p. 483]. This work also connected differential geometry of manifolds and the theory of groups, specifically Lie groups. These connections eventually proved to have a major significance for quantum theory, especially in the theory of elementary particles, which are classified by using Lie groups as symmetry groups, although in connection with the infinite-dimensional spaces. The concept of manifold was also crucial for the development of topology. Initially, it was Riemann's earlier work on Riemann surfaces that had a greater impact. Eventually, topology came to be defined by understanding, which, as I shall explain, follows Riemann, of topological spaces as composed of local neighborhoods of points and (open) subspaces of a given space. It is true that Riemann did not have a concept of topological space. My main concern, however, is the development, transformation of Riemann's concepts (such as manifold) leading to new concepts, such as topological space, which makes Riemann's concepts alive, makes them "live on" in new concepts.

---

[8] Poincaré's extensive (much more extensive than Riemann's) philosophical works (e.g. [28, 29]), while influenced, as were his mathematical works in geometry, by Riemann's Habilitation lecture, may be seen along these lines. I realize that this claim may be challenged, and make it with caution. I would, nevertheless, argue that Riemann's philosophical thinking plays a greater constitutive role in his mathematical thinking than Poincaré's philosophical thinking in his mathematical thinking. The situation is of course different when it comes to physics, which is a major part of Riemann's and Poincaré's mathematical thinking alike, and both made major contributions to physics.

3 Mathematics: Space, Geometry, and the Concept of Manifold

The significance of Riemann's lecture for mathematics, physics, and philosophy, and its impact in all three fields were immense. This impact was delayed until its publication, in 1868, two years after Riemann's death, and fourteen years after it was presented in 1854, although some of Riemann's key ideas contained there and in Riemann's related works became known and had their impact earlier. One can only surmise (a tantalizing surmise!) the consequences for the history of mathematics and physics if the lecture was published more immediately. Riemann opens as follows:

> As is well known, geometry presupposes the concept of space, as well as assuming the basic principles for construction in space. It gives only nominal definitions of these things, while their essential specification appears in the form of axioms. The relationship between these presuppositions is left in the dark; we do not see whether, or to what extent, any connection between them is necessary, or a priori whether any connection between them is even possible.
>
> From Euclid to Lagrange this darkness has been dispelled neither by the mathematicians nor the philosophers who have concerned themselves with it. The reason [ground] [*Grund*] for this is undoubtedly because the general concept of multiply extended magnitudes [*Grösse*], which includes spatial magnitudes, remains completely unexplored. I have therefore first set myself the task of constructing the concept of a multiply extended magnitude from general notions of magnitude. It will be shown that a multiply extended magnitude is susceptible of various metric relations, so that space constitutes only a special case of a triply extended magnitude. From this, however, it is a necessary consequence that the theorems of geometry cannot be deduced from general notions of magnitude, but that those properties that distinguish space from other conceivable triply extended magnitudes can only be deduced from experience. Thus arises the problem of seeking out the simplest data from which the metric relations of space can be determined, a problem that by its very nature is not completely determined, for there may be several systems of simple data that suffice to determine the metric relations of space; for the present purposes, the most important system is that laid down as a foundation of geometry by Euclid. These data are—like all data—not logically necessary, but only of empirical certainty, they are hypotheses [*Hypothesen*]; one can therefore investigate their likelihood, which is certainly very great within the bounds of observation, and afterwards decide on the legitimacy of extending them beyond the bounds of observation, both in the direction of the immeasurably large [*Unmessbargrosse*] and in the direction of the immeasurably small [*Unmessbarkleinen*]. [31, p. 23; translation modified]

These introductory reflections are already profound and far-reaching, and Riemann develops the ideas suggested here quite a bit further in the lecture. First of all, Riemann does not appear to be interested in the axiomatic approach to geometry and is even suspicious of axioms of geometry. In contrast to most previous works on non-Euclidean geometry, the parallel postulate is not the starting point of his investigation. The reason is clearly that the concepts of space and of measuring distances in space are not adequately defined. This is what leaves "the relationships between [axioms] in the dark. We do not see whether, or to what extent, any connection between them is necessary, or a priori whether any connection between them is even possible." This questioning of the axioms of geometry was unusual at Riemann's time, and it was much deeper than customary doubts concerning the parallel postulate. The axiomatic approach to non-Euclidean geometry is, thus, abandoned and even implicitly questioned by Riemann, even though it was this approach that led to the discovery of non-Euclidean geometry by Lobachevsky and Bolyai. This may have been one of the reasons why only Gauss, rather than either Lobachevsky (highly regarded by Gauss) or Bolyai, was expressly invoked in the lecture.[9] It is true that Gauss was ultimately unable to establish a possible existence (in the sense of logical consistency) of non-Euclidean geometry, because, unlike Lobachevsky and Bolyai, he did not do this for the three-dimensional case. In spirit, however, Gauss's work on the geometry of two-dimensional surfaces and his concept of curvature as intrinsic to a given surface was much closer to Riemann. For Riemann, Gauss was pursuing a trajectory of thought better suited for the foundations of geometry and more fruitful for its conceptual development. In his famous extraordinary theorem (*theorema egrerium*, as he called it), Gauss proved that the curvature of a surface, which he defined as well, was intrinsic to the surface. More precisely, the theorem states that the Gaussian curvature of a surface does not change if one only bends the surface but does not stretch it. This means that curvature can be fully determined by measuring angles and distances on the surface itself, without considering the way it is embedded in the ambient (three-dimensional) Euclidean space or, in Riemann's terms, manifold, which makes the Gaussian curvature an intrinsic invariant of a given surface.

One nearly has here a two-dimensional conceptual architecture that suggests and even approaches that of Riemann, although major additional thinking is necessary to give this architecture the type of generality Riemann is able to do. Gauss's theorem suggests that one could see the surface as an independent curved manifold and then to generalize this concept to higher dimensions via "the concept of a multiply extended magnitude," mentioned in this passage and the concept of manifold, which is what Riemann did. These concepts also helped him to generalize to higher dimensions Gauss's concept of curvature. To do so required yet another new concept, another

---

[9] There were other, more extrinsic, reasons, beginning with the fact that Gauss was Riemann's mentor and the chair of his Habilitation committee. Indeed, Gauss selected this topic among three proposed by Riemann (following the rules). The philosopher R. H. Lotze, a fervent opponent of non-Euclidean geometry, was a member of the philosophy faculty, to which Riemann's Habilitation was presented. Later on, Lotze criticized Riemann's approach anyway, as part of his general critique of non-Euclidean geometry (see [16, pp. 222–226] and [33, pp. 97–112]).

great invention of Riemann, the tensor of curvature, and a new form of differential calculus, tensor calculus on manifolds, a generalization of differential calculus. This calculus was fully developed later on, and it played a major role in Einstein's general relativity. The independence of the curvature or of geometry of a given manifold of any dimension from its embedding also allows one to determine, at least in principle, intrinsically whether this space is flat or curved, which is crucial for determining the nature of the physical space we inhabit. For example, as indicated earlier, space is curved in the immediate vicinity of the solar system, because of the gravity of the Sun, planets, and other material entities in the solar system (or locally around other stars), but appears to be on the overage flat on the scale of the observable Universe.[10] In any event, by virtue of inventing his concepts and by using them, Riemann provided a general rigorous grounding to all geometry, Euclidean or non-Euclidean, rather than merely establishing, as Lobachevsky and Bolyai did, the logical possibility of the non-Euclidean geometry of (constant) negative curvature in three dimensions. The absence of a concept, such as that of manifold, leaves us in "the dark," because "we do not see whether, or to what extent, any connection between [axioms] is necessary, or a priori whether any connection between them is even possible."

Riemann's thinking is conceptual-problematic rather than axiomatic-theorematic: he grounds mathematics, as well as physics, in hypotheses and concepts, concepts-problems, such as the concept of manifold and its subconcepts (distance, curvature, tensor, and so forth). The problem of space and geometry is now posed in terms of finding concepts that are necessary to define space and to give it geometry. A general concept of manifold was assumed to be applicable to any possible space, while specific manifolds, flat or curved, define different spaces or subspaces. In this respect, as foundational thinking, that of Riemann is different from that conforming to Hilbert's concept of "foundations" [*Grundlagen*] in the sense of axiomatic foundations, an idea that Hilbert also tried to apply to physics. One of the problems of his famous 1900 list (Problem 6) was in fact that of the development of (mathematized) axiomatic foundations, system(s) of axioms, for physics, on the model of his own *Foundations of Geometry* [13].[11] That such a system is possible is inevitably a hypothesis. It became clear subsequently that the existence of such a system is a hypothesis even in mathematics, and in view of Gödel's incompleteness theorems in 1931, ultimately a wrong hypothesis, insofar as such a system cannot be proven to be free of contradiction, once it is large enough to include arithmetic, as geometry is.

---

[10] As I qualified earlier, at least this is a workable and widely accepted view, widely but not universally. It has never been established definitively or, in any event, agreed upon whether such a determination is ever rigorously possible, as opposed to having a practically effective and possibly, within its proper limits, the best available theory or, as Poincaré would have it, "convention," without making a real claim concerning "the reality underlying space" [31, p. 33]. Einstein had his doubts too, although he was ultimately inclined to accept the possibility of such a determination, at least in principle, as, it appears, was Riemann, but not Poincaré, with whose position Einstein, nevertheless, had to contend and which he tried to accommodate within his own (e.g. [11, pp. 324–328]).

[11] For the development of Hilbert's ideas, as reflected in different editions of the *Grundlagen*, see [4]. In the first version of the book, Hilbert was closer to Riemann, and he later returned to a more Riemannian view of geometry in the wake of general relativity to which he made important contributions.

;. 8 5: 6

3.1 Discrete Conformality of Polyhedral Surfaces

A closed surface S together with a non-empty finite subset of points $V \subset S$ will be called a *marked surface*. A triangulation $\mathcal{T}$ of a marked surface (S, V) is a topological triangulation of S such that the vertex set of $\mathcal{T}$ is V. We use $E = E(\mathcal{T})$, $V = V(\mathcal{T})$ to denote the sets of all edges and vertices in $\mathcal{T}$ respectively. A (Euclidean) *polyhedral metric* on (S, V), to be called a *PL metric* on (S, V) for simplicity, is a flat cone metric on (S, V) with cone points contained in V. We call the triple (S, V, d) a polyhedral surface. All PL metrics are obtained by isometric gluing of Euclidean triangles along pairs of edges. For instance boundaries of convex polytopes are PL metrics on $(\mathbb{S}^2, V)$. The *discrete curvature* of a PL metric d is the function $K_d : V \to (-\infty, 2\pi)$ sending a vertex v to 2π minus the cone angle at v. For a closed surface S, it is well known that the Gauss-Bonnet theorem $\sum_{v \in V} K_d(v) = 2\pi\chi(S)$ holds. If $\mathcal{T}$ is a triangulation of (S, V) with a PL metric d for which all edges in $\mathcal{T}$ are geodesic, we say $\mathcal{T}$ is *geometric* in d and d is a PL metric on $(S, V, \mathcal{T})$. In this case, we can represent the PL metric d by the length function $l_d : E(\mathcal{T}) \to \mathbb{R}_{>0}$ sending an edge to its length. Thus the polyhedral surface (S, V, d) can be represented by $(S, \mathcal{T}, l)$. This is a way of coding a polyhedral surface by a finite-dimensional vector $l_d \in \mathbb{R}^E$.

In general, a polyhedral surface (S, V, d) admits infinitely many different geometric triangulations. However, each polyhedral surface (S, V, d) has a natural *Delaunay triangulation* $\mathcal{T}_d$ which is a geometric triangulation with vertices V such that for each edge, the sum of two angles facing e is at most π. Delaunay triangulations are the most commonly used triangulations in scientific computing. It can be constructed from the Voronoi decomposition $\{R(v)|v \in V\}$ of (S, V, d) as follows. Here a Voronoi 2-cell $R(v)$ for $v \in V$ is defined to be $\{x \in S | d(x, v) \le d(x, v'), \forall v' \in V\}$. The Delaunay tessellation of (S, V, d) is the dual cell decomposition of $\{R(v)|v \in V\}$ whose vertices are V and each 1-dimensional connected component of $R(v) \cap R(v')$ corresponds to a (geodesic) edge from v to v'. A Delaunay triangulation is a subdivision of the Delaunay tessellation into triangles without introducing extra vertices. Any two Delaunay triangulations of (S, V, d) are related by a sequence of Delaunay triangulations such that adjacent ones differ by a diagonal switch along an edge. See for instance [4].

Suppose d is a PL metric on a triangulated surface $(S, \mathcal{T})$ whose edge length function is $l_d : E(\mathcal{T}) \to \mathbb{R}_{>0}$. For a positive function $u : V(\mathcal{T}) \to \mathbb{R}_{>0}$, the vertex scaling of l_d by u is the new function $u * l_d : E(\mathcal{T}) \to \mathbb{R}_{>0}$ such that $u * l_d(vv') = u(v)u(v')l_d(vv')$ where vv' is an edge with end points v, v'. If d, d' are two PL metrics on $(S, \mathcal{T})$, then they differ by a *vertex scaling* if $l_d = u * l_{d'}$ for some $u : V \to \mathbb{R}_{>0}$. The notation of vertex scaling change of PL metrics was introduced in [28] and in [16].

The definition of discrete conformality involves Delaunay triangulations and vertex scaling.

Definition 3.1 ([11]) Two PL metrics d and d' on a marked closed surface (S, V) are *discrete conformal* if there is a sequence of PL metrics $d_1 = d, d_2, ..., d_n = d'$ and a sequence of triangulations $\mathcal{T}_1, \mathcal{T}_2, ..., \mathcal{T}_n$ of (S, V) such that

Fig. 3 Discrete conformal change of PL metrics from an arbitrary tetrahedron to one with constant curvature π. All triangulations involved are Delaunay

(a) each $\mathcal{T}_i$ is Delaunay in d_i,

(b) if $\mathcal{T}_i \neq \mathcal{T}_{i+1}$, then there is an isometry h_i from (S, V, d_i) to (S, V, d_{i+1}) such that h_i is homotopic to the identity map on (S, V), and

(c) if $\mathcal{T}_i = \mathcal{T}_{i+1}$, there is a function $u_i : V \to \mathbb{R}_{>0}$ such that for each edge $e = vv'$ in $\mathcal{T}_i$, the lengths $l_{d_i}(vv')$ and $l_{d_{i+1}}(vv')$ of e in d_i and d_{i+1} are related by

$$l_{d_{i+1}}(vv') = u_i(v)u_i(v')l_{d_i}(vv'), \tag{3.1}$$

i.e., $l_{d_{i+1}} = u_i * l_{d_i}$.

The original motivation in [16] for introducing vertex scaling $u * l_d$ as an approximation to conformal change is the following. Since a PL polyhedral metric l_d on $(S, \mathcal{T})$ is a discretization of a Riemannian metric g and a function $u : V(\mathcal{T}) \to \mathbb{R}_{>0}$ is a discretization of a positive function λ on S, the conformal Riemannian metric λg should be approximated by the PL metric defined by $u * l_d$. The deeper reason for $u * l_d$ to be a discrete conformal change is due to the following observation in Riemannian geometry ([18]). Given a Riemannian metric g on a compact connected manifold M and $\lambda : M \to \mathbb{R}_{>0}$, there exists a constant $C = C(M, g, \lambda)$ such that for any $p, q \in M$, we have

$$|d_{\lambda^4 g}(p, q) - \lambda(p)\lambda(q)d_g(p, q)| \leq Cd_g(p, q)^3$$

where $d_g(p, q)$ is the distance between p, q in the metric g.

The relationship between discrete conformal geometry and hyperbolic geometry is the following [5, 11]. Given a Delaunay triangulated polyhedral surface $(S, \mathcal{T}, d)$ with $V = V(\mathcal{T})$, one can naturally associate to d a cusped hyperbolic metric d^* on $S - V$. Here is the construction. Take a Euclidean triangle τ in $(\mathcal{T}, d)$ considered as the Euclidean convex hull of vertices $v_1, v_2, v_3 \in \mathbb{C}$. Let τ^* be the hyperbolic convex hull $C_{\mathbb{H}}(v_1, v_2, v_3)$ of v_1, v_2, v_3 in the hyperbolic 3-space $\mathbb{H}^3$. Here we consider $\mathbb{C}$ to be in the sphere at infinity of the upper half-space model $\mathbb{C} \times \mathbb{R}_{>0}$ of $\mathbb{H}^3$. Now if σ and τ are two Euclidean triangles in $\mathcal{T}$ glued by a Euclidean isometry f along an edge, since each isometry f of $\mathbb{C}$ extends naturally to an isometry f^* of $\mathbb{H}^3$, we glue

τ^* and σ^* along the corresponding edge by the isometry f^*. In this way, we obtain a complete finite area hyperbolic metric d^* on $S - V$. It follows from the construction that d^* is independent of the choices of the Delaunay triangulations $\mathcal{T}$ used in the construction. It is proved in [11, Theorem 43] that two PL metrics d_1 and d_2 on a closed marked surface (S, V) are discrete conformal in the sense of Definition 3.1 if and only if their associated hyperbolic metrics d_1^* and d_2^* are isometric by an isometry homotopic to the identity (respecting V). Conversely, if S is a closed surface and $\hat{d}$ is a complete finite area hyperbolic metric on $S - V$, then there exists a polyhedral metric d on (S, V) such that $d^* = \hat{d}$. Thus for closed surfaces, there exists a bijection between the space of all discrete conformal classes of polyhedral metrics on (S, V) and the Teichmüller space of cusped metrics on $S - V$.

By this construction, if $\mathcal{T}$ is a Delaunay triangulation of the plane $(\mathbb{C}, d_{st})$ with $V = V(\mathcal{T})$ and d_{st} being the standard flat metric on $\mathbb{C}$, then the associated hyperbolic metric d_{st}^* is the boundary of the convex hull $C_{\mathbb{H}}(V)$ of V in $\mathbb{H}^3$. To see this, we note that codimension-1 faces of $C_{\mathbb{H}}(V)$ correspond to the circum-disks of triangles $\tau \in \mathcal{T}$ due to the Delaunay condition. This shows the relationship between discrete conformal geometry and convex hull construction in the hyperbolic 3-space $\mathbb{H}^3$ and the essential role of Delaunay condition in discrete conformality.

The main theorems proved in [11, 12] are:

Theorem 3.2 ([11]) *Given any PL metric d on a closed marked surface (S, V) and any $K^* : V \to (-\infty, 2\pi)$ such that $\sum_{v \in V} K^*(v) = 2\pi\chi(S)$, there exists a PL metric d^* on (S, V), unique up to scaling and isometries homotopic to the identity map on (S, V), such that*

(a) d^* is discrete conformal to d, and

(b) the discrete curvature K_{d^*} is equal to K^*.

Furthermore, the PL metric d^* can be found by a finite-dimensional variational principle.

For the constant function $K^* = 2\pi\chi(S)/|V|$ in Theorem 3.2, we obtain a constant curvature PL metric d^*, unique up to scaling and isometries homotopic to the identity, discrete conformal to d. We call d^* *the discrete uniformization metric* associated to d. The existence and uniqueness of d^* is a discrete version of the uniformization theorem for closed surfaces.

Theorem 3.2 for the torus $S = \mathbb{S}^1 \times \mathbb{S}^1$ with $K^* = 0$ is equivalent to a theorem of Fillastre [9]. Theorem 3.2 shows that every polyhedral torus $(\mathbb{S}^1 \times \mathbb{S}^1, V, d)$ is discrete conformal to a flat torus $(\mathbb{S}^1 \times \mathbb{S}^1, V, d_{flat})$. Translating it into the language of hyperbolic metrics, we can replace d by any cusped hyperbolic metric $\hat{d}$ on the punctured torus $\mathbb{S}^1 \times \mathbb{S}^1 - V$. The hyperbolic metric associated to $(\mathbb{S}^1 \times \mathbb{S}^1, V, d_{flat})$ is constructed as follows. Take a lattice $L = \mathbb{Z} + \tau\mathbb{Z}$ in $\mathbb{C}$ and consider the boundary $\partial C_{\mathbb{H}}(V^*)$ of the convex hull of V^* in $\mathbb{H}^3$ where V^* is a discrete set in $\mathbb{C}$ invariant under the action of L. Then by the discussion above, d_{flat}^* is isometric to the cusped hyperbolic metric $\partial C_{\mathbb{H}}(V^*)/L$. Furthermore, the lattice L is unique up to complex linear transformations. This is the result proved in [9]. To be more precise, Fillastre proved the following version of convex embedding theorem. For any cusped hyperbolic metric $\hat{d}$ on $\mathbb{S}^1 \times \mathbb{S}^1 - V$, there exist a lattice $L \subset \mathbb{C}$ and a finite set V' in the conformal infinite of the hyperbolic manifold $\mathbb{H}^3/L$ such that $\hat{d}$ is isometric to the boundary of the convex hull of V' in $\mathbb{H}^3/L$.

This shows a close connection between discrete conformal geometry and the convex isometric embedding program of Weyl, Alexandrov, Nirenberg, Pogorelov and others.

Theorem 3.3 ([12]) *Given two PL metrics on a closed marked surface (S, V) such that the lengths of edges are algebraic numbers, there exists an algorithm to decide if they are discrete conformal.*

Theorem 3.3 is proved in our joint work with Ren Guo in [12]. The counterpart of Theorem 3.2 for hyperbolic polyhedral surfaces is also proved in [12].

An important question is whether discrete conformality defined above approximates smooth conformality. To this end, let us recall discrete conformal maps between polyhedral surfaces [5, 18]. Given a closed polyhedral surface (S, V, d). Let d^* be the hyperbolic metric on $S - V$ associated d constructed using ideal hyperbolic triangles associated to Euclidean triangles. The vertical projection of the ideal hyperbolic triangle $\tau^* = C_{\mathbb{H}}(v_1, v_2, v_3)$ to the Euclidean triangle $\tau = C_{\mathbb{E}}(v_1, v_2, v_3)$ produces a piecewise projective homeomorphism Φ_d from $(S - V, d^*)$ to $(S - V, d|_{S-V})$. If d_1, d_2 are two discrete conformal PL metrics on (S, V), then the *discrete conformal map* from (S, V, d_1) to (S, V, d_2) is defined to be (the extension to S) of the composition $\Phi_{d_2} \circ \Psi \circ \Phi_{d_1}^{-1}$ where $\Psi : (S - V, d_1^*) \to (S - V, d_2^*)$ is the isometry homotopic to the identity. Discrete conformal maps are piecewise projective.

Our recent work with Sun and Wu [18] shows that discrete conformality does converge to the smooth conformality. Given a simply connected marked polygonal domain with a PL metric (D, V, d) and three boundary vertices $p, q, r \in V$, let the metric double of (D, V, d) along the boundary be the marked polyhedral 2-sphere $(\mathbb{S}^2, V', d')$. Using Theorem 3.2, one produces a new polyhedral surface $(\mathbb{S}^2, V', d^*)$ such that (1) $(\mathbb{S}^2, V', d^*)$ is discrete conformal to $(\mathbb{S}^2, V', d')$, (2) the discrete curvatures of d^* at p, q, r are $4\pi/3$, (3) the discrete curvatures of d^* at all other vertices are zero and (4) its area is $\sqrt{3}/2$. Thus $(\mathbb{S}^2, V', d^*)$ is the metric double of an equilateral triangle ΔABC of edge length 1. Here A, B, C correspond to p, q, r. Let $F : (\mathbb{S}^2, V', d') \to (\mathbb{S}^2, V', d^*)$ be the associated discrete conformal map sending $\{p, q, r\}$ to $\{A, B, C\}$ respectively. Due to the uniqueness part of Theorem 3.2, we see that $f = F|_D : D \to \Delta ABC$ sending p, q, r to the vertices A, B, C respectively. We call f the *discrete uniformization map* associated to $(D, \mathcal{T}, l, \{p, q, r\})$

Theorem 3.4 ([18]) *Suppose Ω is a Jordan domain in the complex plane with three distinct points p, q, r in the boundary of Ω. There exists a sequence of simply connected polygonal domains $(\Omega_n, \mathcal{T}_n, \{p_n, q_n, r_n\})$ with triangulations $\mathcal{T}_n$ by equilateral triangles of edge lengths converging to 0 where p_n, q_n, r_n are three boundary vertices such that the following hold*

(i) $\Omega_n \subset \Omega_{n+1}$ and $\Omega = \cup_{n=1}^{\infty} \Omega_n$,

(ii) the discrete uniformization maps f_n associated to $(\Omega_n, \mathcal{T}_n, \{p_n, q_n, r_n\})$ converge uniformly on compact sets to the Riemann mapping $f : (\Omega, \{p, q, r\}) \to (\Delta ABC, \{A, B, C\})$.

On the Positive Mass Theorem for Closed Riemannian Manifolds

Andreas Hermann and Emmanuel Humbert

Abstract The Positive Mass Conjecture for asymptotically flat Riemannian manifolds is a famous open problem in geometric analysis. In this article we consider a variant of this conjecture, namely the Positive Mass Conjecture for closed Riemannian manifolds. We explain why the two positive mass conjectures are equivalent. After that we explain our proof of the following result: If one can prove the Positive Mass Conjecture for one closed simply-connected non-spin manifold of dimension $n \geq 5$ then the Positive Mass Conjecture is true for all closed manifolds of dimension n.

1 Introduction

General Relativity is a geometrical theory: the background is a 4-Lorentzian manifold $(\mathcal{M}, G)$ whose metric satisfies:

$$\mathrm{Ric}_G - \frac{1}{2} s_G G = 8\pi T. \tag{1}$$

where Ric_G and s_G denote the Ricci curvature and the scalar curvature of the metric G respectively. The tensor T is the *energy momentum tensor* and contains all the information on the matter and Formula (1) explains how the physical objects (the tensor T) are related to the geometrical background (the curvature). After Gauss' work on the curvature of surfaces which resulted in his famous theorema egregium, it was Riemann who generalized the notion of curvature to higher dimensions by introducing a quantity which today is called the Riemann curvature tensor. In this way he founded the language of modern differential geometry which was later used

by Einstein to formulate the field Eq. (1). Many physical laws can be read through this formula: in particular, it describes gravitation in terms of curvature which at the beginning of the 20th century was the real breakthrough of the theory. This formulation completely denies the existence of a global time which nevertheless has a strong meaning for each human being. One way to overcome this difficulty is to consider an appropriate space-type hypersurface M, which is a Riemannian manifold when equipped with the restriction of the metric G. This manifold M is called a *Cauchy hypersurface* and can be interpreted as a picture of the universe at some fixed time. General Relativity is a deterministic theory: specifying enough data on the chosen Cauchy hypersurface allows to reconstruct the whole spacetime: this is a result by Choquet-Bruhat and Geroch [7]. This is one reason for which many problems can be formulated in terms of Riemannian geometry.

In this survey, we present the Positive Mass Theorem which illustrates what is explained above: the physical question of whether a local positive energy density of an isolated system gives rise to a positive total energy can be formulated as a problem of pure Riemannian geometry. So it is not surprising that in this context, geometrical tools were crucial to (partially) answer this question. On the other hand it is really surprising that the Positive Mass Theorem was the key point in the final argument of R. Schoen for the solution of the Yamabe problem, which was a challenging question in Riemannian geometry and partial differential equations for more than 20 years and which has nothing to do with General Relativity.

In the paper, we will start by introducing the ADM mass of an asymptotically flat manifold and we will explain the reason why it can be interpreted as the total energy of an isolated system. The approach we choose in this text is inspired by the book of Vaugon and the second author [14] where the reader will find many more details. The ADM mass measures how an isolated system affects the trajectories of massless particles evolving far from the system. Note that in the chapter written by Jacques Franchi [8], it is explained how such a system also perturbs Brownian motions (see e.g. the study on Schwarzschild solution). A famous open problem is to know if, under natural physical assumptions, the ADM mass is non-negative together with a rigidity result (for many other interesting rigidity results, the reader may refer to the chapter written by Marc Mars [12]): it should vanish if and only if the spacetime does not contain any matter nor gravity fields and hence is flat.

We will formulate the Positive Mass Conjecture for asymptotically flat manifolds which has been solved in the context of General Relativity (that is, in dimension 3), but which is still considered as open in dimension greater or equal to 8 if the manifold is not spin. Then we will study the mass of closed manifolds, more precisely of manifolds which are compactifications of some asymptotically flat manifolds. As in the chapter written by Jean-Philippe Nicolas [13], the situation appears much clearer in the compact setting giving rise to new applications. We will explain how Schoen defined the mass of a closed Riemannian manifold which can be regarded as the ADM mass of a blown-up manifold. This will give rise to a Positive Mass Conjecture for closed manifolds which was the main point in the last argument for solving the Yamabe problem. It is well known that the Positive Mass Conjectures for closed and for asymptotically flat manifolds are actually equivalent: the proof of this equivalence is essentially contained in the work of Schoen, Lohkamp or Lee-Parker [16, 17, 19]. But, even if all the ingredients of the proof are in the literature, it is quite difficult to find a reference where this equivalence is explicitly stated and proved. We do it in this paper.

In the last paragraph we present our recent results which reduce the Positive Mass Conjecture to proving that it holds for every metric on one fixed closed non spin and simply connected manifold in each dimension.

2 ADM Mass in General Relativity

The goal of this paragraph is to explain how we can define the energy of an isolated system in General Relativity. We will not be very precise in this section: our goal is mainly to explain the physical considerations which lead to the definition of the ADM Mass. For more information on this subject, the reader may refer to [14].

2.1 Modeling Isolated Systems in General Relativity

An *isolated system* is a physical system contained in a "bounded region". Obviously, the notion of "bounded region" should be understood in the sense "bounded in space" and not in time. The general idea is that the gravitational field induced by the system decreases as the distance to the system increases and vanishes at infinity.

It is generally considered as natural that the spacetime $(\mathcal{M}, G)$ (a 4-Lorentzian manifold satisfying Eq. 1) is *globally hyperbolic*, i.e. possesses a *Cauchy hypersurface* M, which means that any inextensible causal curve of $\mathcal{M}$ meets M exactly once. The manifold $\mathcal{M}$ is then homeomorphic to $M \times \mathbb{R}$ and the hypersurfaces $M \times \{t\}$ can be interpreted as "pictures of the universe" at some time t as was proved by Geroch [9]. Bernal-Sánchez [6] were able to strengthen this result by showing that $\mathcal{M}$ is diffeomorphic to $M \times \mathbb{R}$. With this assumption, it is natural to impose that:

- the energy-momentum tensor T is compactly supported in each hypersurface $M \times \{t\}$ which means that the system is contained in a bounded region of space;
- the metric g becomes flat at infinity, in a sense to be made precise, which means that the gravitational field decreases far from the system.

The first assumption is in general too strong. For example it is not satisfied for the Reissner-Nordström metric. Actually, in all physical applications, we just need to consider the second assumption: it does not imply the first one but implies that the energy-momentum tensor T vanishes at infinity. A good way to take into account these considerations is to assume that the spacetime $(\mathcal{M}, G)$ is *asymptotically flat*: there exists a coordinate system (t, x, y, z) such that the hypersurfaces $t =$ constant correspond to Cauchy hypersurfaces and such that in these coordinates we have

On Local Characterization Results in Geometry and Gravitation

Marc Mars

Abstract An important problem in differential geometry and in gravitation is to identify metrics in a fully coordinate independent manner. In fact, the very foundation of Riemannian geometry is based on the existence of a tensor, the Riemann or curvature tensor, which vanishes if and only if the metric is locally flat. Many other such local characterizations of metrics are known. The aim of this article is to present a brief selection of them as an example of the fruitful interplay between differential geometry and gravity.

1 Introduction

Albert Einstein's great insight was that the gravitational interaction was a manifestation of the curvature of spacetime. With this radically new point of view, Einstein gave physical reality to non-euclidean geometries, introduced in Bernhard Riemann's inaugural lecture "Über die Hypothesen, welche der Geometrie zu Grunde liegen" in 1854 [47], about sixty years before Einstein's theory of general relativity was founded. It is most remarkable that Riemann himself, in the last paragraphs of his dissertation, had already realized that the grounds for the metric relations in physical space had to come from binding forces that act upon it, in a view that was already radically different from Newton's conception of space and time as a fixed and invariable entity completely unaffected by physical processes occurring within it. Building on Riemann's mathematical ideas, Einstein could transform his outstanding physical intuition into one of the most elegant physical theories of all times. One of the fundamental consequences of this theory is that differential geometry is not only a fundamental branch of mathematics but also a basic tool for doing physics, and the

DOI 10.1007/978-3-319-60039-0_18

interplay between these two aspects has given a tremendous boost to this scientific discipline.

One of the basic questions that differential geometry has to address is: when are two Riemannian manifolds[1] isometric? Obviously this is also a fundamental question in general relativity, as it addresses the question: when two spacetimes are physically equivalent? This question can be stated, and it is relevant, also at the local level: When are two Riemannian manifolds locally isometric? In fact, answering this question in the case of Euclidean space led Riemann to the introduction of his curvature tensor and to the statement that the vanishing of the curvature at every point is the necessary and sufficient condition for the metric being (locally) flat. The vanishing of the Riemann curvature tensor as a local characterization of Euclidean space is one of the most fundamental results in Riemannian geometry. A natural question is whether similar local characterizations for other geometries also exist. A satisfactory local characterization of a geometry is a very useful tool both in geometry and in general relativity (or any other geometric theory of gravitation). Many results along those lines are known, some coming from pure geometry and some from gravitational theory. The purpose of this chapter is to review a selection of such characterizations as an example of the fruitful interplay between differential geometry and gravity. It must be emphasized that I have no intention of presenting a comprehensive review of known results in this area of research. This would require much more space and a more knowledgeable author. The selection is based solely on my own taste, so many interesting local characterizations will be left out, for which I apologize in advance.

2 Classical Characterizations

Local characterizations involve the notion of local isometry, in the following standard sense. Two Riemannian manifolds $(\mathcal{M}_1, g_1)$ and $(\mathcal{M}_2, g_2)$ are locally isometric if given any point $p \in \mathcal{M}_1$, there exist a connected, open neighbourhood $\mathcal{U}_p$ of p and a smooth map $\Phi_p : (\mathcal{U}_p, g_1|_{\mathcal{U}_p}) \longrightarrow (\mathcal{M}_2, g_2)$ which is an isometry onto its image. Often it is necessary to extend this definition to a situation when $(\mathcal{M}_2, g_2)$ is not a single space but belongs to a class $\{(\mathcal{M}_2^{\mathfrak{a}}, g_2^{\mathfrak{a}})\}$. In this case, the target of the local isometry Φ_p is allowed to depend on p. All manifolds considered here are finite dimensional, smooth, Hausdorff and connected.

As already mentioned, the most important local characterization of a geometry is that of Euclidean space or, more generally, of flat space of signature (p, q), $\mathbb{M}^{p,q} := (\mathbb{R}^{p+q}, \eta^{(p,q)} = -\sum_{i=1}^{p}(dx^i)^2 + \sum_{i=p+1}^{p+q}(dx^i)^2)$. Depending on the point of view, the Riemann tensor can be defined in several ways. The modern approach is to define the curvature operator as

---

[1] My convention here is that a Riemannian metric is not necessarily positive definite, but can have any non-degenerate signature. The term *strictly Riemannian* is reserved for the positive definite case.

$$\mathrm{Curv}^g(X,Y)Z = \left(\nabla_X\nabla_Y - \nabla_Y\nabla_X - \nabla_{[X,Y]}\right)Z, \qquad X,Y,Z \in \mathfrak{X}(\mathcal{M})$$

where ∇ is the metric-compatible, torsion-free connection associated to g

$$\mathrm{Riem}^g(W,Z,X,Y) = \langle W, \mathrm{Curv}^g(X,Y)Z\rangle, \qquad W,X,Y,Z \in \mathfrak{X}(\mathcal{M})$$

where $\langle\, ,\, \rangle$ denotes scalar product with g. In terms of this tensor Riemann's characterization of flat space is

Theorem 2.1 (Local characterization of flat space, Riemann [47]) *A Riemannian manifold $(\mathcal{M}, g)$ is locally isometric to the flat space with the same dimension and signature if and only if $Riem^g = 0$.*

Being intended to all faculty members, Riemann's lecture contains hardly any formula (see Chap. 4 in Spivak's comprehensive treatise [73] for a detailed exposition of Riemann's lecture) so no detailed proof of this claim is given there. Not even an explicit form of the Riemann tensor in a general coordinate system appears there. Following Spivak [73], such an explicit expression, and a proof of the fact that its non-vanishing is an obstruction for a metric being locally flat, appeared first in an unpublished paper, known as the *Commentatio*, submitted in 1861 to the Paris Academy and which appeared in the second edition of the collected works of Riemann [62]. However, as emphasized in [26] (see also [34]), this unpublished paper was primarily concerned with a problem of heat conduction proposed by the Academy in 1858, so its primary concern was not in Geometry, and it is debatable whether our modern understanding of the field might be biasing the interpretation of its results (see the interesting discussion on this *Commentatio* in [34] and references therein). In any case, an explicit expression of what we now know as the Riemann tensor appeared for the first time in this unpublished paper by Riemann. The first explicit proof that the vanishing of this tensor is sufficient for a metric being (locally) flat was given by Elwin Bruno Christoffel [17]. The proof of Theorem 2.1 is so central in differential geometry that many different proofs have been given. Spivak's treatise includes seven explicit proofs, which very nicely illustrate how differential geometry has evolved over the years from a discipline where the use of coordinates was central, to a mature theory where geometric objects fully independent of coordinates are the basic entities.

Another fundamental local characterization of Riemannian manifolds involves manifolds of constant sectional curvature. Recall that the sectional curvature of a two-plane $\Pi \subset T_p\mathcal{M}$, $p \in (\mathcal{M}, g)$ with non-degenerate induced first fundamental form h is defined as

$$K(p;\Pi) = \frac{\mathrm{Riem}^g(X,Y,X,Y)}{h(X,X)h(Y,Y) - h(X,Y)^2}, \qquad \{X,Y\} \text{ any basis of } \Pi.$$

The sectional curvature $K(p;\Pi)$ agrees with the Gauss curvature at p of the surface ruled by geodesics starting at p with tangent vector $X \in \Pi$. A Riemannian manifold has constant curvature k if $K(p;\Pi) = k$ for all $p \in \mathcal{M}$ and all non-degenerate

$ * &* N51E16*. +* &* * 1 *
37,.3 * .*1 *. & U 1

plane $\Pi \in T_p\mathcal{M}$. A well-known lemma by Friedrich Schur [70] asserts that any Riemannian manifold with sectional curvature $K(p, \Pi) = k(p)$ independent of Π is in fact of constant curvature.

For any $k \in \mathbb{R}$, define the manifold $\mathbb{M}_k^{(p,q)}$ as the subset $B(K) \subset \mathbb{R}^{p+q}$

$$B(K) := \{x \in \mathbb{R}^{p+q}; 1 + \frac{k}{4}(\eta_{ij}^{(p,q)} x^i x^j) > 0\},$$

endowed with the metric g_k given by

$$g_k := \frac{1}{\left(1 + \frac{k}{4}(\eta_{ij} x^i x^j)\right)^2} \eta_{ij}^{(p,q)} dx^i dx^j,$$
$$\eta^{(p,q)} := \mathrm{diag}(\underbrace{-1, \ldots, -1}_{p}, \underbrace{1, \ldots, 1}_{q})$$

(it is easily seen that $B(K)$ is connected for all values of k and all signatures (p, q)). Spaces of constant curvature are all isometric to this space. This is already mentioned without proof in Riemann's inaugural lecture [47] and it was also known to Eugenio Beltrami [4].

Theorem 2.2 *Let $(\mathcal{M}, g)$ be a Riemannian manifold of constant sectional curvature k and signature (p, q). Then $(\mathcal{M}, g)$ is locally isometric to $\mathbb{M}_k^{(p,q)}$.*

Riemannian manifolds of constant curvature are also locally characterized by the condition that the Killing algebra of $(\mathcal{M}, g)$ has maximal dimension. Recall that a Killing vector is a vector field $\xi \in \mathfrak{X}(\mathcal{M})$ satisfying $\mathcal{L}_\xi g = 0$ where $\mathcal{L}$ denotes Lie derivative. The set of Killing vectors $\mathcal{K}$ in a manifold defines a finite-dimensional algebra (with respect to the Lie bracket) called Killing algebra. If the manifold has dimension n, the Killing algebra has dimension $\dim(\mathcal{K}) \leq \frac{n(n+1)}{2}$ and whenever equality is attained, the manifold is called maximally symmetric. A classical result by Luigi Bianchi [6] asserts that maximally symmetric spaces are precisely those of constant sectional curvature.

Theorem 2.3 (Bianchi [6]) *A Riemannian manifold $(\mathcal{M}, g)$ is maximally symmetric if and only if it has constant sectional curvature.*

Another important class of Riemannian manifolds singled out by the properties of its isometry group is the class of Riemannian symmetric spaces. These are defined as Riemannian manifolds $(\mathcal{M}, g)$ such that, at any point $p \in \mathcal{M}$ there exists an isometry $\Psi_p : \mathcal{M} \to \mathcal{M}$, $\Psi_p^\star(g) = g$ satisfying $\Psi_p(p) = p$ and $d\Psi_p|_p = -\mathrm{Id}|_p$, i.e. this isometry leaves p invariant and reverses any vector at p. Riemannian symmetric spaces can be locally characterized in terms of the Riemann tensor, as first proved by Élie Cartan.

Theorem 2.4 (Locally symmetric spaces, Cartan [12]) *A Riemannian manifold $(\mathcal{M}, g)$ is locally isometric to a Riemannian symmetric space if and only if the curvature tensor satisfies*

$$\nabla Riem^g = 0.$$

The Riemann tensor can be decomposed in its trace and its trace-free parts. The trace part defines the Ricci tensor $\mathrm{Ric}^g(X, Y) = \mathrm{tr}_g \mathrm{Curv}^g(X, \cdot)Y$ from which the scalar curvature is defined as $\mathrm{Scal}^g = \mathrm{tr}_g \mathrm{Ric}^g$. Useful tensors defined in terms of the Ricci tensor are the Schouten tensor Sch^g (in dimension $n > 2$) and the Einstein tensor Ein^g:

$$\mathrm{Sch}^g := \frac{1}{n-2}\left(\mathrm{Ric}^g - \frac{1}{2(n-1)}\mathrm{Scal}^g g\right), \qquad \mathrm{Ein}^g = \mathrm{Ric}^g - \frac{1}{2}\mathrm{Scal}^g.$$

The Weyl tensor is the trace-free part of the Riemann tensor, defined as

$$\mathrm{Weyl}_g = \mathrm{Riem}^g - \mathrm{Sch}^g \odot g$$

where $\odot$ is the Kulkarni-Nomizu product on symmetric tensors

$$\begin{aligned}(A \odot B)(X_1, X_2, X_3, X_4) =& A(X_1, X_3)B(X_2, X_4) - A(X_1, X_4)B(X_2, X_3) \\ &+ A(X_2, X_4)B(X_1, X_3) - A(X_2, X_3)B(X_1.X_4).\end{aligned}$$

Hermann Weyl introduced [79] the tensor named after him in an attempt to find a theory of gravitation invariant under scale (conformally invariant). The Weyl tensor has the fundamental property that $\mathrm{Weyl}_{\Omega^2 g} = \mathrm{Weyl}_g$ where $\Omega \in C^\infty(\mathcal{M}, \mathbb{R}^+)$. Thus, it vanishes automatically in any locally conformally flat space. Schouten [66] proved that the vanishing of this tensor is also sufficient in dimension $n \geq 4$ (in dimension $n = 2$ the Weyl tensor is not defined and in $n = 3$ it vanishes identically). As is well-known, in dimension $n = 2$ any space is locally conformally flat. In dimension three, the necessary and sufficient condition for local conformal flatness was obtained by Émile Cotton [16] in terms of the vanishing of the so-called Cotton tensor, which in dimension $n > 2$ is defined as

$$\mathrm{Cott}(X, Y, Z) = (n-2)\left((\nabla_Z \mathrm{Sch})(X, Y) - (\nabla_Y \mathrm{Sch})(X, Z)\right),$$

where $X, Y, Z \in \mathfrak{X}(\mathcal{M})$. This tensor is conformally invariant in any space with vanishing Weyl tensor (hence always in dimension three). Summarizing the discussion above, we have

Theorem 2.5 (Locally conformally flat spaces, Cotton, Weyl and Schouten) *A Riemannian manifold* $(\mathcal{M}^n, g)$ $n \geq 3$ *of signature* (p, q) *is locally isometric to a conformally flat space* $(\mathbb{R}^n, \Omega^2 \eta^{(p,q)})$, $\Omega \in C^\infty(\mathbb{R}^n, \mathbb{R}^+)$ *if and only if*

(i) If $n = 3$*, the Cotton tensor vanishes.*
(ii) If $n \geq 4$*, the Weyl tensor vanishes.*

3 Local Characterizations of the Schwarzschild and Kruskal Spacetimes

Among indefinite Riemannian manifolds, the Lorentzian ones (i.e. with signature $(-, +, \dots, +)$) play a fundamental role in physics, as they describe spacetimes. For the purposes of this article by **spacetime** we simply mean a Lorentzian manifold[2] $(\mathcal{M}, g)$ of dimension $n \geq 2$. In Einstein's theory of General Relativity the spacetime geometry is linked to the energy-momentum contents of the non-gravitational fields via the Einstein field equations

$$\mathrm{Ein}^{g} = \chi T$$

where χ is a coupling constant depending on Newton's gravitational constant G and T is the energy-momentum tensor of the fields. In particular, a spacetime is *vacuum* whenever its Einstein tensor (or equivalently its Ricci tensor) vanishes.

With the exception of the flat Minkowski spacetime, perhaps the most important spacetime in general relativity is the Schwarzschild spacetime of mass $M \in \mathbb{R}$ found by Karl Schwarzschild [67] shortly after the Einstein field equations were proposed (see [77] for the corresponding solution in higher dimensions). To be specific, by this solution we mean the manifold $\mathcal{M}_{\rm Sch} := \mathbb{R} \times (r_0, \infty) \times \mathbb{S}^{m-1}$ $m \geq 3$, where $r_0 = 0$ if $M \leq 0$ and $r_0 = (2M)^{\frac{1}{m-2}}$ if $M > 0$, endowed with the metric (in global coordinates $(t, r) \in \mathbb{R} \times (r_0, \infty)$)

$$g_{\rm Sch} = -\left(1 - \frac{2M}{r^{m-2}}\right) dt^2 + \left(1 - \frac{2M}{r^{m-2}}\right)^{-1} dr^2 + r^2 \gamma^{\mathbb{S}^{m-1}} \tag{1}$$

in units where $8\pi G = (m-1)\omega_{m-1}$ and $\gamma^{\mathbb{S}^k}$ is the standard metric of the k-sphere $\mathbb{S}^k$ and ω_k the corresponding total volume. The Schwarzschild spacetime is spherically symmetric and vacuum. Spherically symmetric means that the spacetime admits an action of $SO(m)$ as a group of isometries with orbits being either spacelike codimension-two surfaces or points. The fact that the metric (1) is defined also in another manifold, namely $\mathbb{R} \times (0, r_0) \times \mathbb{S}^2$ was found (for $m = 3$) independently by Droste [20] and Hilbert [40].

The Schwarzschild spacetime of mass $M \neq 0$ admits a maximal extension that keeps the properties of being spherically symmetric and vacuum. This is the Kruskal spacetime, which is defined as follows. Let $\mathcal{M}_{\rm Kr} = \mathcal{U} \times \mathbb{S}^{m-1}$ where $\mathcal{U} \subset \mathbb{R}^2$ is an open set defined by the inequality $\mathcal{U} := \{(u, v) \in \mathbb{R}^2; r(u \cdot v) > 0\}$ where $r := (a, b) \subset \mathbb{R} \to \mathbb{R}$ is the maximal solution of the differential equation

$$\frac{dr}{dx} = \frac{1}{(m-2)\,x}(2|M|)^{\frac{1}{m-2}}\left(1 - \frac{2M}{r^{m-2}}\right). \tag{2}$$

---

[2] Usually, the notion of spacetime requires also time-orientability, but this is irrelevant for the local characterization theorems we are describing here.

For $M < 0$, the maximal domain of definition does not include $x = 0$. However, for $M > 0$, the solution to this equation extends smoothly through $x = 0$ and has a non-zero gradient at $x = 0$. The Kruskal metric g_{Kr} is defined on $M_{\text{Kr}} = \mathcal{U} \times \mathbb{S}^{m-1}$ and reads

$$g_{\text{Kr}} = \frac{4}{(m-2)^2} |2M|^{\frac{2}{m-2}} \frac{1 - 2Mr(u \cdot v)^{2-m}}{uv} du dv + r(u \cdot v)^2 \gamma^{\mathbb{S}^{m-1}}.$$

The case $m = 3$ is best known, as it corresponds to the original extension by Martin Kruskal [46] (also found independently by Georges Szekeres [75]) of the Schwarzschild spacetime of dimension $n = 4$. In this case the ODE (2) for $M > 0$ can be integrated in simple terms as

$$uv = \left(1 - \frac{r}{2M}\right) e^{\frac{r}{2M}} \quad \Longrightarrow \quad g_{\text{Kr}} = -\frac{32M^3}{r(uv)} e^{-\frac{r}{2M}} du dv + r^2(uv) \gamma^{\mathbb{S}^{m-1}}.$$

The original Schwarzschild spacetime corresponds to the domain $\{v > 0\} \cap \{u < 0\}$ and describes the exterior of the black hole spacetime. The conformal diagram of this exterior domain can be found in [56] along with interesting results on scattering and peeling of test fields on this and other backgrounds. The process of relativistic diffusion on the Schwarzschild spacetime is discussed in [30].

The most important local characterization theorem in gravitational theory is the Birkhoff theorem [7]. This theorem appears in the literature in two different guises, either as a local characterization theorem of the Kruskal spacetime, or as a statement that under suitable circumstances, a spherically symmetric spacetime must admit an additional Killing vector.[3] The two guises appear because the Schwarzschild spacetime was obtained under the assumptions of vacuum, spherically symmetry, time-independence and the implicit assumption that ∇r is spacelike. Birkhoff's proof that any vacuum, spherically symmetric spacetime admits an additional Killing vector and the fact that this Killing is timelike whenever ∇r is spacelike, provides therefore a local characterization theorem for the Schwarzschild metric among vacuum spherically symmetric spacetimes. In fact, the first result concerning the existence of an additional static symmetry is due to Jebsen [42] in a work virtually forgotten for a long time despite the fact that due credit was given e.g. in [33, 69]. This work has been brought back to light in more recent times, first in [64] and later in [19], see [43] and references therein for further details on the discovery of the Schwarzschild spacetime and Birkhoff's theorem.

Historical remarks aside, the fact of the matter is that the Schwarzschild and Kruskal spacetimes are unique among vacuum spherically symmetric n-dimensional Lorentzian spacetimes. This result has enormous physical significance as it means that, like in Newtonian theory, a spherically symmetric gravitational field outside its sources depends on a single constant, namely the total mass of the configuration. It also states that spherical sources cannot emit gravitational radiation, even if they are themselves evolving. The precise local characterization result is as follows.

---

[3] The second guise is sometimes stated that spherically symmetric, say vacuum, spacetimes are static, but this is clearly not true in this generality as the Kruskal extension admits no global timelike Killing vector, see [22] where this fact is discussed in some more detail.

Theorem 3.1 (Local characterization of the Kruskal spacetime) *Let* $(\mathcal{M}^n, g)$ *be a Lorentzian* n*-dimensional space such that the group* $SO(n-1)$ *acts as a group of isometries with orbits which are either codimension-two spacelike submanifolds or points. If* $(\mathcal{M}, g)$ *is vacuum, then there exists* $M \in \mathbb{R}$ *such that* $(\mathcal{M}, g)$ *is locally isometric to the Kruskal spacetime* $(\mathcal{M}_{Kr}, g_{Kr})$ *of mass* M*. Let* $r : \mathcal{M} \to \mathbb{R}$ *be defined as*

$$r(p) = \left(\frac{|\mathcal{O}_p|}{\omega_{n-2}} \right)^{\frac{1}{n-2}}$$

where $\mathcal{O}_p$ *is the orbit of* $SO(n-1)$ *containing* p*,* $|\mathcal{O}_p|$ *its* $(n-2)$*-volume and* ω_{n-2} *the* $(n-2)$*-volume of the round unit sphere* $\mathbb{S}^{n-2}$*. If* $\langle \nabla r, \nabla r \rangle_p \neq 0$*, then* $(\mathcal{M}, g)$ *is locally isometric near* p *to the Schwarzschild spacetime* $(\mathcal{M}_{Sch}, g_{Sch})$ *of mass* M*.*

Analogous local characterization theorems of spherically symmetry spacetimes exist for many other matter models, including Λ-vacuum (i.e. $\mathrm{Ric}^g = (n-1)\Lambda g$, $\Lambda \in \mathbb{R}$), electrovacuum, Einstein-Maxwell-dilaton and many others. A detailed description of all such result is beyond the scope of this note, see [68] and references therein for results in this direction.

3.1 Characterization of Spherically Symmetric Spacetimes with an Additional Killing Vector

As already mentioned, the Birkhoff theorem for the vacuum spherically symmetric spacetime can be viewed as a local characterization result of the Kruskal spacetime or as a statement that spherically symmetric vacuum spacetimes admit an additional local isometry with generator orthogonal to the spherically symmetric orbits and which is timelike on regions where ∇r is spacelike. Viewed from this perspective, the Birkhoff theorem is a particular case of a result proved by Eiesland in [23] (and announced at the Eastern Meeting of the American Mathematical Society at Chicago in 1921 [24] shortly before the result by Birkhoff appeared). The theorem by Eiesland, although correct, uses a rather strange convention of the Einstein tensor. In terms of the usual definition $\mathrm{Ein}^g = \mathrm{Ric}^g - \frac{1}{2}\mathrm{Scal}^g g$ this theorem has been recently quoted in [76]. We follow the notation in this reference (with a couple of typo corrections).

Theorem 3.2 (Eiesland [23]) *The necessary and sufficient conditions that a locally spherically symmetric Lorentzian manifold with line-element*

$$ds^2 = -A^2 dt^2 + B^2 dr^2 + C^2 \left(d\theta^2 + \sin^2 \theta d\phi^2 \right)$$

A, B and C being arbitrary, non-zero functions of t and r, and C not a constant, shall admit a one-parameter group of isometries generated by a vector field $K = k_0(t,r)\partial_t + k_1(t,r)\partial_r$ are

$$A^2 Ein^t_r = \frac{2\Psi'}{C}\partial_r C \partial_t C,$$
$$A^2B^2\left(Ein^t_t - Ein^r_r\right) = \frac{2\Psi'}{C}\left[A^2(\partial_r C)^2 + B^2(\partial_t C)^2\right],$$

where $\Psi = \Psi(C)$ is some differentiable function of C, or a constant, and Ein^r_t, Ein^t_t etc. denote the components of the Einstein tensor (with one index raised) in the coordinate basis $\{\partial_t, \partial_r, \partial_\theta, \partial_\phi\}$. Under these conditions the Killing field K is, up to a constant multiple, given by

$$k_0(t,r) = -\frac{1}{e^\Psi AB}\partial_r C, \qquad k_1(t,r) = \frac{1}{e^\Psi AB}\partial_t C.$$

This theorem has been extended in [65] to Einstein spaces which are locally warped products $g = h + r^2\gamma$, where h is a Lorentzian metric and r a positive non-constant function on a two-dimensional space $\mathbb{Q}$, and γ is a metric on an m-dimensional manifold Σ^m, $m \geq 2$. Let us state and prove a theorem that generalizes Eiesland's result to arbitrary warped space with two-dimensional base.

Theorem 3.3 *Let $(\mathcal{M}, g)$ be locally isometric to a warped product space $(\mathbb{Q} \times \Sigma^m, g)$ $(m \geq 2)$, i.e. $g = h + r^2\gamma$, where r is a smooth positive function and h a metric on a two-dimensional manifold $\mathbb{Q}$ and (Σ, γ) is a (pseudo-)Riemannian manifold. Let $\epsilon = 1$ if h is Lorentzian and $\epsilon = -1$ if h is positive or negative definite.*

Assume that there is no open set in $\mathbb{Q}$ where $|\nabla r|^2_h$ vanishes identically. Then $(\mathcal{M}, g)$ admits a Killing vector $K \in \mathfrak{X}(\mathbb{Q})$ if and only if, away from the points where $|\nabla r|^2_h = 0$, there exists a smooth, nowhere-zero, function $H(r)$ such that

$$Ric^g|_{\mathbb{Q}} - \frac{1}{2}tr_h\left(Ric^g|_{\mathbb{Q}}\right)h = \frac{(m-1)H'}{2Hr}\left(dr \otimes dr + \epsilon dr^\star \otimes dr^\star\right)$$

where $Ric^g|_{\mathbb{Q}}$ is the restriction of the Ricci tensor of g to the tangent planes of $\mathbb{Q}$ and $\star$ is the Hodge dual in $(\mathbb{Q}, h)$. Moreover, the one-form $\boldsymbol{K} := h(K,\cdot)$ is $\boldsymbol{K} = H(r)dr^\star$

Proof It is immediate to check that a vector field K tangent to the $\mathbb{Q}$ factor is Killing if and only if K is Killing for $(\mathbb{Q}, h)$ and $K(r) = 0$. On the open set where dr is not null for the metric h (which is dense on $\mathbb{Q}$ by assumption), dr and $dr^\star$ are a basis of the cotangent space of any point in $\mathbb{Q}$. We work on this open (possibly disconnected) set from now on. Note that $\langle dr, dr^\star\rangle = 0$ and $\langle dr, dr\rangle = -\epsilon\langle dr^\star, dr^\star\rangle$ where $\langle\cdot,\cdot\rangle$ denotes scalar product with h. The condition $K(r) = 0$ is equivalent to the existence of a function $H \in C^\infty(\mathbb{Q}, \mathbb{R})$ such that $\boldsymbol{K} = H dr^\star$ or, in index notation $K_i = H\boldsymbol{\eta}_{ij}\nabla^j r$ where $\boldsymbol{\eta}$ is the volume form of h and ∇ denotes the Levi-Civita derivative of h. It is known (and follows e.g. by explicit computation) that

$$\mathrm{Ric}^g|_{\mathbb{Q}} = K^h h - \frac{m-1}{r}\mathrm{Hess}_h r$$

where the Hessian of a functions is, as usual, defined by $(\mathrm{Hess} f)(X, Y) = \langle \nabla_X \mathrm{grad}\, f, Y \rangle$ and where K^h is the Gauss curvature of h. Let us denote by $\mathring{\mathrm{Ric}}^g_{\mathbb{Q}}$ the trace-free part of $\mathrm{Ric}^g|_{\mathbb{Q}}$ so that we have

$$\mathrm{Hess}_h r = -\frac{r}{m-1}\mathring{\mathrm{Ric}}^g_{\mathbb{Q}} + f h \tag{3}$$

where f is a scalar function whose form does not concern us. The Killing equations for K read

$$\begin{aligned} 0 = \nabla_i K_j + \nabla_j K_i &= \eta_{jl} \nabla_i H \nabla^l r + H \eta_j{}^l \nabla_i \nabla_l r + \eta_{il} \nabla_j H \nabla^l r + H \eta_i{}^l \nabla_j \nabla_l r \\ &= \eta_{jl} \left(\nabla_i H \nabla^l r - \frac{Hr}{m-1} (\mathring{\mathrm{Ric}}^g_{\mathbb{Q}})^l{}_i \right) + \eta_{il} \left(\nabla_j H \nabla^l r - \frac{Hr}{m-1} (\mathring{\mathrm{Ric}}^g_{\mathbb{Q}})^l{}_i \right) \end{aligned}$$

after inserting (3) and noticing that the term proportional to f drops. An endomorphism A^i_j satisfying $\eta_{jl} A^l_i + \eta_{il} A^l_j = 0$ must be proportional to the identity. Thus, there exists a function F on $\mathbb{Q}$ such that

$$\nabla_i H \nabla_j r - \frac{Hr}{m-1} (\mathring{\mathrm{Ric}}^g_{\mathbb{Q}})_{ij} = F h_{ij} \qquad \Longrightarrow \qquad A = \frac{1}{2} \langle \nabla H, \nabla r \rangle \tag{4}$$

where the implication follows simply by taking trace. The antisymmetric part of (4) implies that there exists a function $\hat{H} : I \to \mathbb{R}$ such that $H = \hat{H} \circ r$. We make the usual abuse of notation of writing simply $H(r)$. Note that H cannot vanish anywhere (on the open set $|\nabla r|^2_h \neq 0$) because if $H = 0$ at one point p, then (4) implies that H' also vanishes at that point, and the Killing K vanishes at p together with its covariant derivative, which can only happen if K is identically zero.

A basis for trace-free symmetric tensors is given by $dr \otimes dr + \epsilon dr^\star \otimes dr^\star$ and $dr \otimes dr^\star + dr^\star \otimes dr$. Expanding $\mathring{\mathrm{Ric}}^g_{\mathbb{Q}}$ in this basis and using $h = \frac{1}{|\nabla r|^2_h}(dr \otimes dr - \epsilon dr^\star \otimes dr^\star)$ it follows that

$$\mathring{\mathrm{Ric}}^g_{\mathbb{Q}} = \frac{(m-1)H'}{2Hr} \left(dr \otimes dr + \epsilon dr^\star \otimes dr^\star \right),$$

as stated in the theorem. □

Eiesland's Theorem 3.2 follows from this result because on open connected sets where $|\nabla r|^2_h \neq 0$, we can choose $H > 0$ (possible after reversing the Killing K). Writing $H = e^{-\Psi}$, Theorem 3.2 is recovered after a straightforward calculation.

Bernhard Riemann and His Work

Lizhen Ji

Abstract This chapter attempts to give a brief summary of the life and work of Riemann. It tries to address the following issues: the influence of his education and early life on his work, and a summary of his major works and an overview of his work, and the general impact of his work through the concepts and terminology named after him.

1 Introduction

Bernhard Riemann (1826–1866) was one of the most original mathematicians in the history of mathematics. Though he had written only a small number of papers, he changed the way we view and do mathematics. For example, to get a taste of his impact, it suffices to think of several concepts named after him: Riemann surfaces, Riemann-Roch theorem, Riemann zeta function, and Riemannian geometry.

Specifically, before Riemann, complex functions were studied on domains of the complex plane $\mathbb{C}$, and the issue of analytic continuation and the ensuing problem of multi-valuedness were complicated. Now after the work of Riemann, the proper way to understand a complex analytic function and its analytic continuation, in particular to understand properly an algebraic function defined by an algebraic equation, is to consider its associated Riemann surface. One can even turn things around so that Riemann surfaces become the more basic spaces, and holomorphic functions on them can be viewed as maps between Riemann surfaces. (In the language of categories, Riemann surfaces become objects and holomorphic maps become morphisms between the spaces.) This thinking led to the Riemann mapping theorem, which in turn led to the uniformization theorem for Riemann surfaces, which is one of the most important theorems in mathematics. Consequently, geometry and analysis are now intimately connected. Riemann proved the crucial part of Riemann's inequality in the Riemann-Roch Theorem. In doing this, he initiated the theory of algebraic topology and made topology an essential part of geometric function theory and geometric

analysis. The Riemann-Roch theorem also motivated the important index theories for higher dimensional manifolds and algebraic varieties.

Similarly, the Riemann zeta function brought the methods of complex analysis into analytic number theory, and it is now hard to imagine what remains if we remove ideas of complex analysis, for example, the Riemann zeta function and generalized Riemann zeta functions, from analytic number theory. Generalized Riemann zeta functions include L-functions which are also crucial in algebraic number theory and arithmetic geometry. For example, without them, it is almost impossible to formulate the celebrated Langlands program.

In differential geometry, the idea of Riemannian metric, Riemannian connections and their non-positive definite generalizations in the theory of relativity are indispensable to most people working in the subject, and higher dimensional generalizations of the Riemannian mapping theorem can also be expressed in terms of Riemannian geometry.

Besides his geometric and global view, Riemann's work has several other features. Riemann's intuitive reasoning played a crucial role in his work. It might fall somewhat short of a rigorous proof, but the brilliant ideas in his works are so much clearer, because his work is not overly filled with lengthy computations (though heavy computations were important for him to gain his understanding and intuition). One example of Riemann's intuitive reasoning is his application of Dirichlet's principle to various problems such as the Riemann mapping theorem and the Riemann-Roch theorem.

Integration between mathematics and physics runs through a large part of Riemann's work. According to Klein [8, p. 167], this integration is the source of inspiration for Riemann:

> he endeavored again and again to find a general mathematical formulation for the laws underlying all natural phenomena.... *these physical views are the mainspring of Riemann's purely mathematical investigations.*

Riemann had a bigger perspective and was a better philosopher than most mathematicians. For example, his paper on the hypothesis which lies at the basis of geometry contains a substantial philosophic part. Not only the intrinsic geometry is important to him, its relation to reality, or to the real space we live in, is also important to him. According to Freudenthal [4], Riemann was

> one of the most profound and imaginative mathematicians of all time, he had a strong inclination to philosophy, indeed, was a great philosopher. Had he lived and worked longer, philosophers would acknowledge him as one of them.

Riemann was also capable of doing very extensive and heavy calculations. This can be confirmed by some existing calculating sheets or scratching papers used by him at the Nachlass of Riemann in the Historical Library of the University of Göttingen. This is consistent with Riemann's ability and joy in doing computation when he was a young boy. Riemann resembled Gauss in the aspect of powerful computation. Computation was crucial to Riemann, and his intuition, deep insights and understanding might result from, but is certainly supported by, his extensive computations.

Besides his originality, Riemann was also broad. His work covered almost all major subjects in mathematics. It is important and interesting to get an overview of the work of Riemann. This task is probably beyond the ability of any single person, though several people including Klein [8], the editor of the Russian edition of Riemann's Collected works, and the author of the book [9], had tried. Narasimhan edited the 1990 edition of Riemann's collected works [16]. In the preface, he also summarized and commented on some of Riemann's major works after writing "No one person is capable of a full analysis of Riemann's work, its history, its development and its influence on mathematics."

In this book, there are several chapters devoted to summarizing and analyzing some aspects of Riemann's works, for example, [5, 12–14, 18]. On the other hand, in this chapter, we want to give a brief overview of all major aspects of Riemann's work and life. Given the long lasting impact of Riemann on the development of mathematics, it is worthwhile to view Riemann and his work from different perspectives. This chapter should complement other chapters of this book. We also hope to understand better, or give some explanation for, his work from the perspective of his education and interaction with others.

2 Riemann's Work I: His Best Known Works

As we mentioned earlier, Riemann made deep contributions to many different subjects. In the opinion of most mathematicians, he is probably best known for his work in the following four subjects:

1. Complex analysis.
2. Real analysis.
3. Riemannian geometry.
4. Number theory.

We will start with the most famous result of his work during his life time, and then summarize some of his major results in the above four subjects.

1.a. *Abelian functions and the Jacobian inversion problem.*
Given what most people know about Riemann, it might be surprising to point out that during Riemann's life time, he first became famous and probably was best known for his solution of the Jacobi inversion problem for Riemann surfaces (or algebraic functions) of higher genus.[1] Though this particular result of Riemann is

---

[1] As it is known, the theory of elliptic integrals motivated the theory of Abelian integrals. One basic insight in the theory of elliptic integrals is to consider the inverse of an elliptic integral. The general framework for Abelian integrals on a fixed compact Riemann surface is the map via integration of holomorphic 1-forms from the group of divisors of degree 0 to the Jacobian variety of the Riemann surface. To invert this map, we need to identify its image. One version of the Jacobi inversion problem, as presented in most modern textbooks on Riemann surfaces, asks to prove that this map is surjective. The full version asks, in addition, for a precise description of the inverse images of this map.

Chapter 6
Teleparallelism

According to FEYNMAN (1962/63), “gravity is that field which corresponds to a gauge invariance with respect to displacement transformations.” Taking this literally would favor Einstein’s teleparallelism equivalent of GR, which has been recast (MIELKE 1992; MIELKE et al. 1996) into a Yang–Mills-type *gauge theory of translations*. On the other hand, Ashtekar’s reformulation ASHTEKAR (1986, 1991) of general relativity (GR) is a complex reformulation that essentially projects out the right and left helicity modes of the graviton.

6.1 Chiral Teleparallelism

Originally, these complex variables were developed in the Hamiltonian approach. In the equivalent Lagrangian formulation, this change of variables is more simply induced by a *generating function* (DOLAN 1989; MIELKE 1990) that involves a boundary term dC_{TT} constructed from a *translational Chern–Simons term* (CS) multiplied by the imaginary unit. This is facilitated in the framework of Riemann–Cartan (RC) geometry, where the coframe ϑ^{α} surfaces as a soldered *translational* gauge potential (MIELKE et al. 1993; TRESGUERRES & MIELKE 2000) having $T^{\alpha} := D\vartheta^{\alpha}$ as its corresponding translational field strength, i.e., torsion.

Via a sort of duality rotation, CS-type boundary terms dC transform into a viable gravitational Lagrangian: the standard Hilbert action of general relativity (GR), or, as was already suggested by EINSTEIN (1928), a theory with *teleparallelism* ($\mathrm{GR}_{\|}$). Recently, it was shown (MIELKE 1992) how a complex Yang–Mills-type version of $\mathrm{GR}_{\|}$ arises by a canonical transformation induced via dC_{TT}. Moreover, the naturalness of Sparling’s energy complex in this approach has been pointed out; cf. DUBOIS-VIOLETTE & MADORE (1987).

Mathematical Physics Studies, DOI 10.1007/978-3-319-29734-7_6

Since the resulting chiral version of gravity is surprisingly close to Yang–Mills, we can adopt a related Hamiltonian formulation in which the Poisson brackets for the constraints are on a par with the local Poincaré algebra. Interestingly enough, the corresponding Gauss constraint of spatial diffeomorphisms is annihilated, on the operator level, by a state vector that is proportional to the exponentiated translational CS term, thus improving on MIELKE (1998, 1999). Classical configurations dominating this action are *torsion instantons*, thus hinting at another close formal parallelism of internal Yang–Mills with chiral $\mathrm{GR}_{\|}$. Moreover, this similarity with quantum gauge theories paves the way to a Becchi–Rouet–Stora–Tyutin (BRST) quantization of gravity based on *translational* ghost operators. The correlation function for Wilson loops is known (GUADAGNINI et al. 1990) to yield, to first order, the Gauss self-linking number. For the full expectation value, the generalized Jones polynomial related to the Kauffman bracket of knots (BRÜGMANN et al. 1992) arises once a *framing* has been chosen. In the case of *chiral teleparallelism*, the loops automatically carry an orthonormal frame along their path, a concept that was realized much earlier by CARTAN (1924). Thus such *Cartan circuits* winding around torsion instantons may provide another clue to a field quantization of gravity based on chiral $\mathrm{GR}_{\|}$.

One may speculate that teleparallel ("flat") spacetime may reveal, on the Planck scale $\ell := \sqrt{8\pi\hbar G_{\mathrm{N}}/c^3} \simeq 10^{-33}$ cm, a topologically rich spectrum of dislocations and knotlike loops.

6.2 Parity-Violating Topological Invariants in Gravity

In the one-dimensional harmonic oscillator model (MIELKE 1998) with q as generalized coordinate, a *canonical transformation* can be induced by a boundary term derived from the *Chern–Simons* (CS)-type term $\mathscr{C} = q^2/2$ as *generating function*. After quantization, the corresponding operator $\mathscr{S} = \exp(-\mathscr{C}) = \exp\left(-q^2/2\right)$ induces a well-known renormalization of the Schrödinger wave function. On the other hand, for diffeomorphism-invariant topological field theories, HOROWITZ (1989) has shown that $\Psi = N \exp\left(i\theta \int \underline{\mathscr{C}}\right)$ is, up to an overall factor, the unique solution of the Hamiltonian constraints. It is worth investigating whether this carries over to gravity:

Since the Poincaré group $P := \mathbb{R}^4 \rtimes SO(1,3)$ is the semidirect product of translations and Lorentz rotations, its gauging leads to the two associated Chern–Simons (CS) three-forms:

$$C_{\mathrm{TT}} := \frac{1}{2\ell^2}\left(\vartheta^\alpha \wedge T_\alpha\right) = -\frac{(-1)^{\mathrm{sig}}}{2\ell^2}\, {}^*\mathscr{A}, \qquad (6.2.1)$$

F . , . 0 1 3 . +* * 1* * 3 1 * * 3 0
1 * & 0 7, * * & * 1 1 * 21 * 3 * * *
0 1 & . (5 AA 0 AAA6

$$
\begin{aligned}
C_{\mathrm{RR}} &:= -\mathrm{Tr}\left(\Gamma \wedge \Omega - \frac{1}{3}\Gamma \wedge \Gamma \wedge \Gamma\right) \\
&= -\frac{1}{2}\left(\Gamma_\alpha{}^\beta \wedge R_\beta{}^\alpha + \frac{1}{3}\Gamma_\alpha{}^\beta \wedge \Gamma_\beta{}^\gamma \wedge \Gamma_\gamma{}^\alpha\right) .
\end{aligned}
\tag{6.2.2}
$$

They are *translational* and Lorentz-rotational CS terms, where $\mathscr{A} := {}^*(\vartheta_\alpha \wedge T^\alpha) = \mathscr{A}_i dx^i$ is the *axial torsion* one-form. In the first *translational* CS three-form, there necessarily occurs a fundamental length ℓ for dimensional reasons.

In a gauge theory with the linear group $SL(5, \mathbb{R})$ as structure group, containing the de Sitter group $\mathrm{SO}(1, 4)$ or $\mathrm{SO}(2, 3)$ as a subgroup, both CS three-forms are intimately interrelated: via a Wigner–Inönü-type contraction, the CS decomposition

$$
\hat{C} = C_{\mathrm{RR}} - 2C_{\mathrm{TT}} \tag{6.2.3}
$$

into linear and translational terms was realized already in HEHL et al. (1995) (see footnote 31), and later by NIEH (2007), MERCURI (2009). In contrast to the metric-free Pontryagin form, in the NY term (6.2.4), a metric $g_{\alpha\beta}$ is needed to raise and lower the indices, for instance in $T_\alpha = g_{\alpha\beta}T^\beta$.

The corresponding boundary or Nieh–Yan term (NIEH & YAN 1982; GUO et al. 1999) can be obtained by exterior differentiation

$$
dC_{\mathrm{TT}} \equiv \frac{1}{2\ell^2}\left(T^\alpha \wedge T_\alpha + R_{\alpha\beta} \wedge \vartheta^\alpha \wedge \vartheta^\beta\right), \tag{6.2.4}
$$

whereas the corresponding Pontryagin term

$$
dC_{\mathrm{RR}} = -\mathrm{Tr}\ (\Omega \wedge \Omega) = \frac{1}{2}\, R^{\alpha\beta} \wedge R_{\alpha\beta} \tag{6.2.5}
$$

is more familiar. Its integration is proportional to the Pontryagin number. Both are *parity violating* (MIELKE 1999).

Whereas the Pontryagin term (6.2.5) is a topological Lagrangian whose variation returns the second Bianchi identity

$$
DR_{\alpha\beta} \equiv 0, \tag{6.2.6}
$$

the less well known torsion identity (6.2.4) is based, after exterior multiplication by ϑ_α, on the first Bianchi identity

$$
DT^\alpha \equiv R_\beta{}^\alpha \wedge \vartheta^\beta \tag{6.2.7}
$$

in Riemann–Cartan (RC) geometry.

II

CIRCLES

The circle, in various guises, occurs in many branches of mathematics. In this chapter we shall consider those properties which have the habit of appearing in different contexts. Our methods will be mixed. We shall use Euclidean geometry or analytical geometry, according to our needs at the time. We begin with the consideration of certain one-to-one mappings of the plane onto itself, and the product of these mappings. (See 0.11.) Later on we study inversion, which is only one-to-one onto if we cut out a point of the plane, or better still, add a point to the plane.

12.1 The nine-point circle

We have already encountered this circle (§7.3). It is a circle which passes through nine points intimately connected with any given triangle *ABC*. (We shall not be using vector methods, and we shall use the customary notation for the points connected with a triangle). The nine-point circle is the first really exciting one to appear in any course on Euclidean geometry which goes far enough.

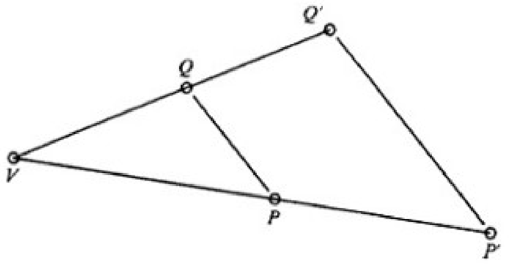

Fig. 12.1

To prove the existence of the nine-point circle of a triangle, we make use of *a one-to-one mapping* of the Euclidean plane onto itself. This mapping is called *a central dilatation*. We choose a point *V*, and call it *the center of the dilatation*

(Fig 12.1).

If P is any point in the plane its image, or map P' is found by choosing the unique point P' which lies on VP, is on the same side of V as is P, and is such that $\overline{VP'} = k\overline{VP}$ where k is a fixed real positive number. If $P = V$, we define V' to be V.

This mapping is evidently one-to-one. It is also called *a central similarity*. It will occur again later (§41.5) as one of the fundamental mappings of the Euclidean plane onto itself. Here we are only interested in the case when k is positive, and when the point P moves on a circle, center O (Fig. 12.2). If O' is the map of O, then the triangles VOP and $VO'P'$ are similar, so that $\overline{VP'} = k\overline{VP}$, Since O is a fixed point, and $| OP | = r$, the radius of the circle on which P moves, we deduce that P' moves on a circle, center O' of radius kr.

Let us now recall some properties of a triangle ABC which we wish to use (Fig 12.3). We know that the perpendiculars AD', BE' and CF' from the vertices A, B and C onto the opposite sides all pass through a point H, the orthocenter (§7.2). If AD' is produced to cut the circumcircle of triangle ABC again at D, it is easy to see that $\overline{HD'} = \overline{D'D}$. since $\measuredangle BCD = \measuredangle BAD$(angles on the same arc), and $\measuredangle BCH$ is complementary to $\measuredangle B$, and is therefore equal to $\measuredangle BAD$. Hence the triangles HCD', DCD' are congruent, and $\overline{HD'} = \overline{D'D}$.

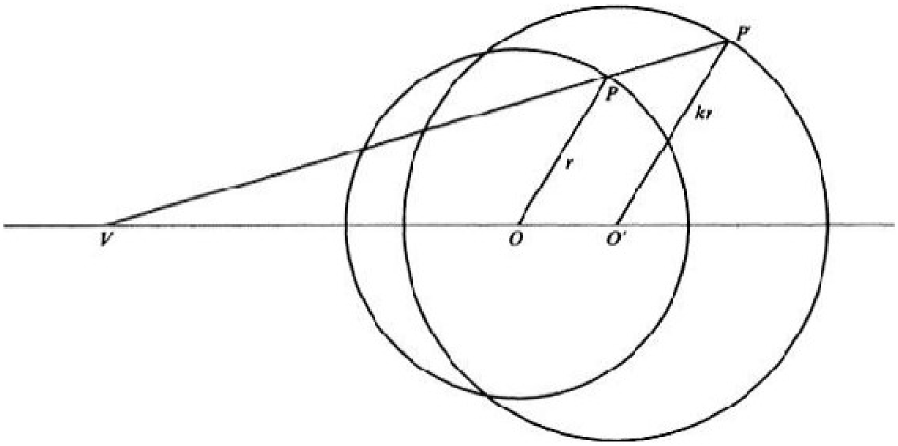

Fig. 12.2

Now consider the central dilatation which has vertex H, and for which $k = 1/2$. This maps every point P on P', where $\overline{HP'} = \overline{HP}/2$. Let P move around the circumcircle of triangle ABC. We know that P' will move on a circle of half the radius, with center bisecting HO, where O is the center of the circumcircle of triangle ABC. This circle will pass through the midpoints of HA, HB and HC, since *A*, *B* and *C* are on the circumcircle, and also through the points *D*′, *E*′ and *F*′, since we have shown that *D*′ is the midpoint of *HD*. We have therefore found *six* points connected with the triangle *ABC* which lie on a circle.

Now, a circle is uniquely determined if we are given *three* non-collinear points through which it must pass. Consider the triangle *BHC*. Its orthocenter is *A*. By what we have just proved, there is a circle which passes through *D*′, *E*′ and *F*′, the feet of the perpendiculars from *H*, *B* and *C* onto the opposite sides *BC*, *HC* and *HB*, and through the midpoints of *AH*, *AB* and *AC*, *A* being the orthocenter of triangle *HBC*. But there is only one circle through the points *D*′, *E*′ and *F*′. Hence the circle connected with triangle *ABC* which passes through *D*′, *E*′ and *F*′ and the midpoints of *HA*, *HB* and *HC* also passes through the midpoints of *AB* and *AC*. By considering the triangle *HCA* we see that this same circle also passes through the midpoint of *BC*. We have therefore established the existence of a circle which passes through the midpoints of the sides of triangle *ABC*, the midpoints of *HA*, *HB* and *HC*, and through the feet of the perpendiculars from the vertices of *ABC* onto the opposite sides. We also know that its center bisects *OH*, and that its radius is half that of the circumcircle.

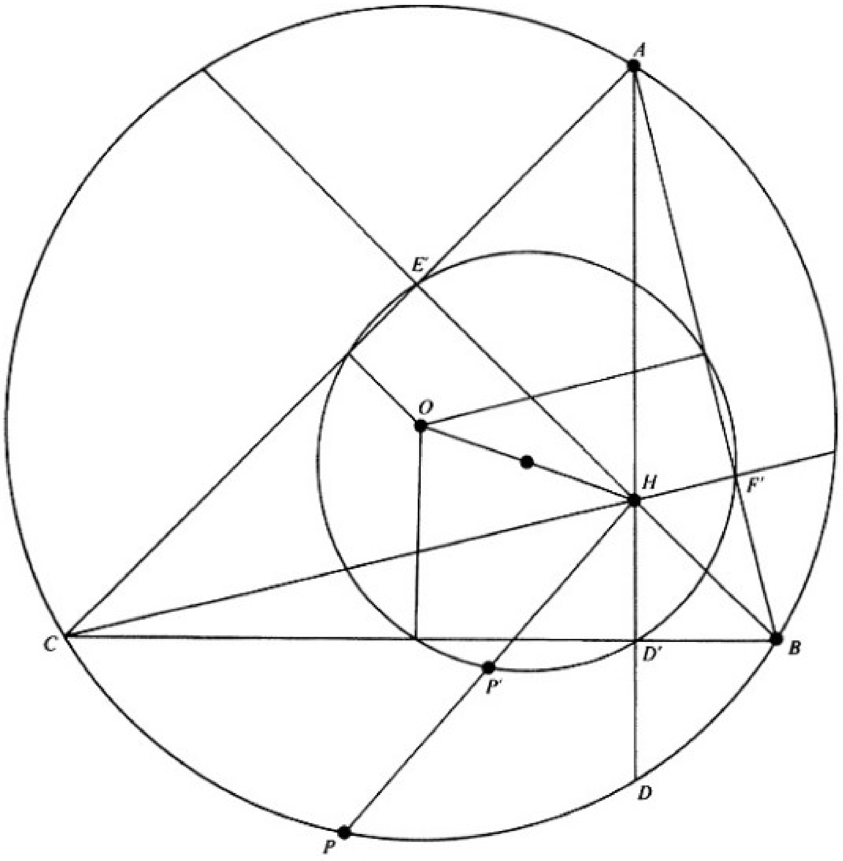

Fig. 12.3

This is a first example of the use of a mapping to establish a theorem in geometry. We shall come across other examples fairly soon.

Exercises

12.1 Let AO (where O is the circumcenter of triangle ABC) intersect the circumcircle again in Y. Prove that $BHCY$ is a parallelogram, and deduce that the circle through six points found above also passes through the midpoints of BC, CA and AB.

12.2 Let A', B', C' be the midpoints of BC, CA and AB, and let L', M' and N' be the midpoints of HA, HB and HC. Using the theorem that the join of the midpoints of two sides of a triangle is parallel to the third side prove that both $B'C'M'N'$ and $C'A'N'L'$ are rectangles, and deduce that $A'L'$, $B'M'$ and $C'N'$ are three diameters of one circle. Prove that this circle passes through the feet of the perpendiculars, D', E' and F' from A, B and C onto the sides BC, CA and AB, and so complete another proof of the existence of the nine-point circle.

12.3 We know that *N*, the center of the nine-point circle, bisects *OH* (in the notation of §12.1). Deduce from Exercise 12.1 that if *A′* is the midpoint of *BC*, then since *A′* bisects *HY* and *O* bisects *AY* $\overline{AH} = 2\overline{OA'}$. Now join *O* to *H* and show that the centroid of *ABC*, which is at the point *G* on *AA′*, where $\overline{AG} = 2\overline{GA'}$, must lie on *OH*, and $\overline{HG} = 2\overline{GO}$. (The line which contains the circumcenter, centroid, nine-point center and orthocenter of triangle *ABC* is called the *Euler line* of triangle *ABC*.)

12.4 If *L′* is the midpoint of *AH*, show that *AL′A′O* is a parallelogram, so that | *A′L′* | = | *OA* | = radius of circumcircle of *ABC*, and therefore, since *A′* and *L′* both lie on the nine-point circle, *A′L′* must be a diameter of the nine-point circle. (Compare Exercise 12.2.)

12.5 On the arc *A′D′* of the nine-point circle, take the point *X* one-third the way from *A′* to *D′*. Take similar points *Y* and *Z* on the arcs *B′E′* and *C′F′*. Show that the triangle *XYZ* is equilateral. (Hint: the triangle *X′Y′Z′* which corresponds to *XYZ* under the mapping, center *H*, which maps the circumcircle onto the nine-point circle, must be equilateral.)

12.6 If *A′*, *B′*, *C′* be the respective midpoints of the sides *BC*, *CA* and *AB* of a triangle *ABC*, show that *O*, the circumcenter of *ABC*, is the orthocenter of *A′B′C′*. From the parallel case of the Desargues Theorem (§5.1) show that *AA′*, *BB′*, *CC′* pass through a point *G*. (This, is of course, the centroid of *ABC*). There is a dilatation, center *G*, which maps *ABC* onto *A′B′C′*. Show that *H* maps onto *O*, and deduce that *H*, *G* and *O* are collinear, and $\overline{HG} = 2\overline{GO}$. (See Exercise 12.3.) Deduce also that $\overline{AH} = 2\overline{OA'}$.

12.7 Show that *O* is the incenter of the triangle *PQR* produced by drawing tangents to the circumcircle of *ABC* at the vertices. Show also that *H* is the incenter of the triangle *D′E′F′*, where *D′* is the foot of the perpendicular from *A* onto *BC*, *etc.* Prove that the sides of *PQR* and *D′E′F′* are respectively parallel. Deduce that the joins *D′P*, *E′Q*, *F′R* pass through a point *V*, the center of the dilatation which maps *D′E′F′* on *PQR*, and that *V* lies on *OH*, the Euler line of *ABC*. Deduce further that since the circumcenter of *D′E′F′* is the nine-point center of *ABC*, the circumcenter of *PQR* lies on the join of *V* to the nine-point center of *ABC*, that is, on the Euler line of *ABC*.

13.1 The centers of similitude of two circles

If *V* is a center for a dilatation which lies outside a circle $\mathscr{C}$ of center *O* (see Fig 13.1), we know already that the image $\mathscr{C}'$ of $\mathscr{C}$ is a circle center *O′*, where $\overline{VO'} = k\overline{VO}$, and that the radius of $\mathscr{C}'$ $=kr_r$,where *r* is the radius of $\mathscr{C}$:. The points *P* and *P′* lie on the same side of *V*, the radii *OP* and *O′P′* are parallel, and $\overline{VO}:\overline{VO'}$ =1:k= of radius of $\mathscr{C}$ If *P*, *Q* are distinct points on $\mathscr{C}$ and *P′*, *Q′* the image points, the chord *PQ* is parallel to the chord *P′Q′*. If *Q* moves towards *P* on $\mathscr{C}$ the point *Q′* moves towards *P′* on $\mathscr{C}$. Hence each of the two tangents from *V* to $\mathscr{C}$ will be a tangent to $\mathscr{C}$ and *V* is the intersection of two common tangents to $\mathscr{C}$ and to $\mathscr{C}$ each tangent having $\mathscr{C}$ and $\mathscr{C}'$ on the same side of it. We call such tangents *external* common tangents.

If *V* does not lie outside $\mathscr{C}$ all the statements made above continue to be true, but there are no tangents from *V* to $\mathscr{C}$ and therefore none from *V* to $\mathscr{C}'$. (see Fig 13.2).

These situations can be reproduced with any two given circles. Let us suppose that we are given two circles $\mathscr{C}$ and $\mathscr{C}'$ with distinct centers O and O'. Draw parallel radii OP and $O'P'$ *in the same sense* through O and O' respectively. Then the join of the points P and P' will intersect the line of centers OO' of the two circles in a fixed point V (unless the circles are of equal radii), and $\overline{VO}:\overline{VO'}$ of $\mathscr{C}$ radius of $\mathscr{C}'$. This point V is called *the external center of similitude* of $\mathscr{C}$ and $\mathscr{C}'$. It divides OO' *externally* in the ratio of the radii of $\mathscr{C}$ and $\mathscr{C}'$. We see that $\mathscr{C}$ can always be mapped onto $\mathscr{C}'$ by a central dilatation, vertex V.

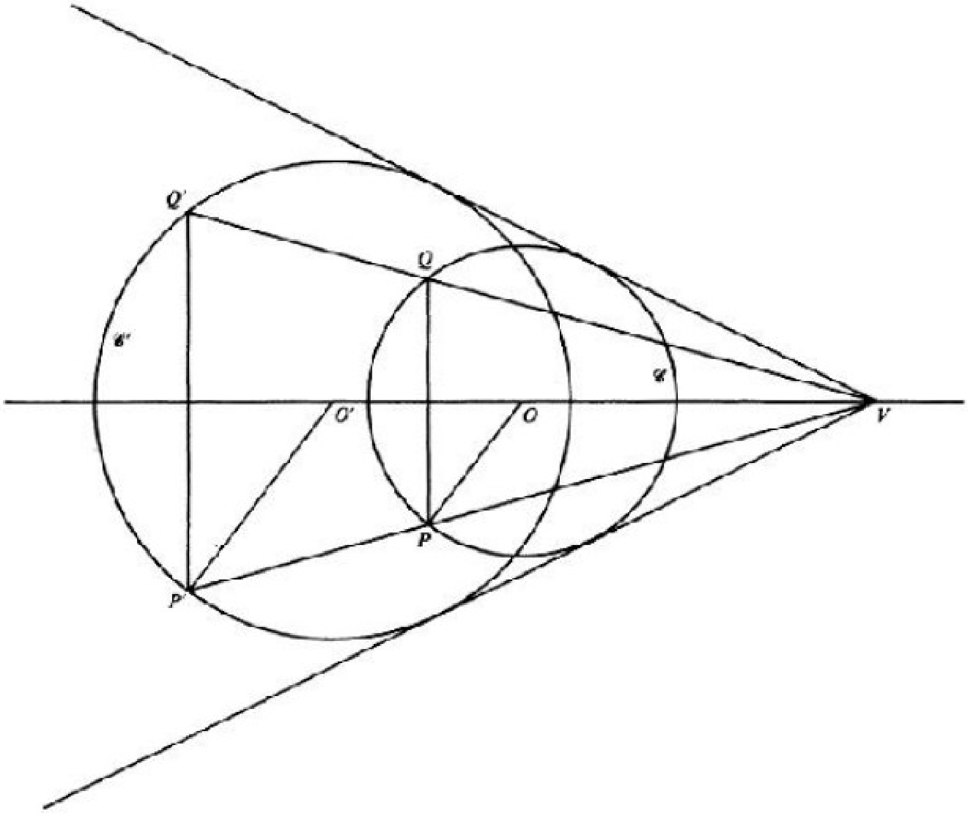

Fig. 13.1

If, in our description of central dilatations, we choose the image point P' so that P and P' are on *opposite* sides of V (Fig 13.3), the map of a circle is still a circle, the center of the circle $\mathscr{C}$ is the map O' of the center O of $\mathscr{C}$ and this time V divides OO' internally in the ratio of the radii of $\mathscr{C}$ and $\mathscr{C}'$ and OP and $O'P'$ are parallel but in opposite directions. If V lies outside $\mathscr{C}$ the tangents from V to $\mathscr{C}$ are also tangents to $\mathscr{C}'$ but $\mathscr{C}$ and $\mathscr{C}'$ lie on opposite sides of each common tangent.

The tangents are called *internal common tangents*, or *transverse* common tangents.

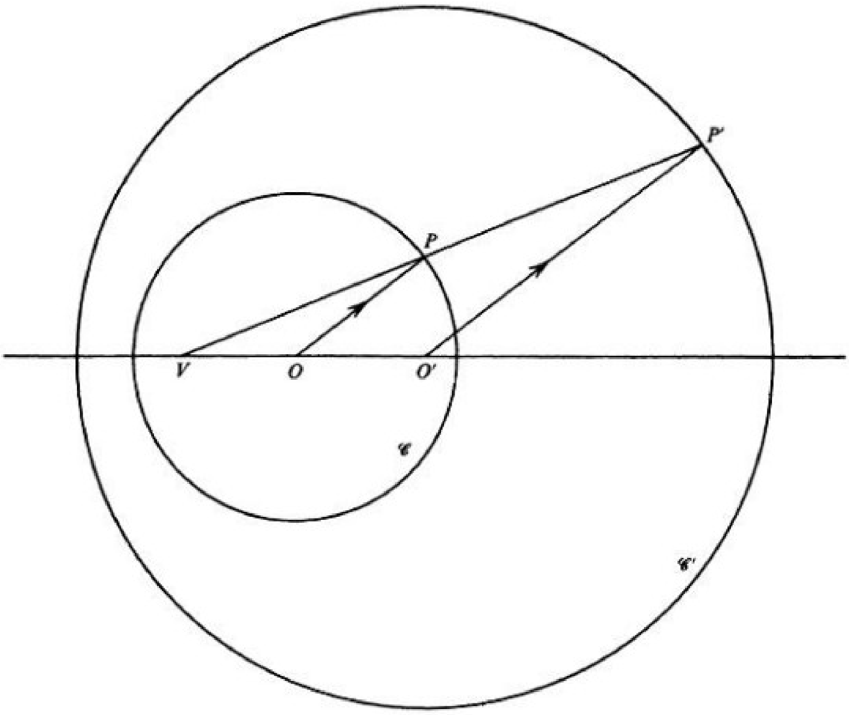

Fig. 13.2

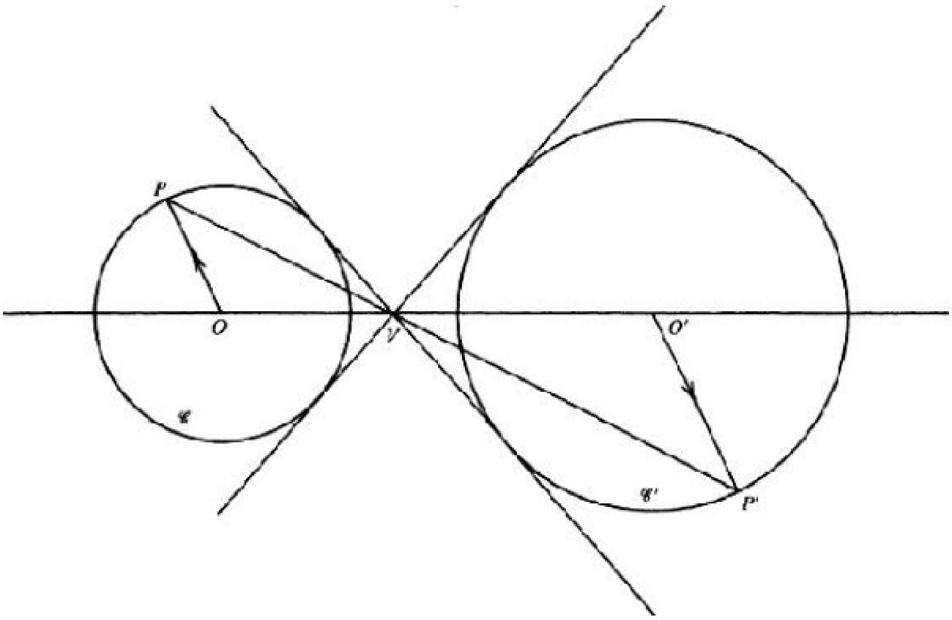

Fig. 13.3

Again, if we are given any two circles $\mathscr{C}$ and $\mathscr{C}'$ with centers O and O' the above situation can be reproduced. Draw parallel radii OP and $O'P'$ in *opposite senses* through O and O' respectively. Then the join of the points P and P' will intersect the line of centers OO' in a fixed point V, and $|VO| : |VO'|$ = radius of $\mathscr{C}$:radius of $\mathscr{C}'$. This point V is called *the internal center of similitude of* $\mathscr{C}$ *and* $\mathscr{C}'$. It divides OO' *internally* in the ratio of the radii of $\mathscr{C}$ and $\mathscr{C}'$.

Exercises

13.1 Show that if the circles $\mathscr{C}$ and $\mathscr{C}'$ are concentric, the common center must be considered to be both the internal and external center of similitude. Where are the internal and external centers when: (*a*) $\mathscr{C}$ and $\mathscr{C}'$ touch *externally*, lying on opposite sides of the tangent at the point of contact and: (*b*) $\mathscr{C}$ and $\mathscr{C}'$ touch *internally*, lying on the same side of the tangent at the point of contact?

13.2 If we have three circles in the plane, no two with equal radius, and the centers forming a triangle, prove that the six centers of similitude (two from each pair of circles) lie in sets of three on four lines. (Two proofs are possible, one using the Desargues Theorem (§5.2), and the other the Menelaus Theorem (§4.1.)) The four lines are called *axes of similitude of the three circles*.

13.3 In the preceding Exercise show that the join of two internal centers of similitude always passes through an external center of similitude. What deduction can you make about the join of the points of contact of a circle which touches two other circles externally?

Since C and C' are fixed points, where is P when the left-hand sum is a minimum? Show that when this is the case the angles subtended at P by BC and AB and AC are each 120°.

25.1 A fixed point theorem

Theorem *If* $\mathscr{C}$ *and* $\mathscr{D}$ *are two non-intersecting circles, any circle* $\mathscr{E}$ *which cuts them both orthogonally passes through two fixed points on their line of centers.* (See Fig 25.1.)

Proof. We anticipate the result of §29.4 which indicates that we may choose our coordinate axes so that the equations of the given circles $\mathscr{C}$ and $\mathscr{D}$ are respectively:

$$X^2 + Y^2 + 2gX + p^2 = 0, X^2 + Y^2 + 2gX + p^2 = 0,$$

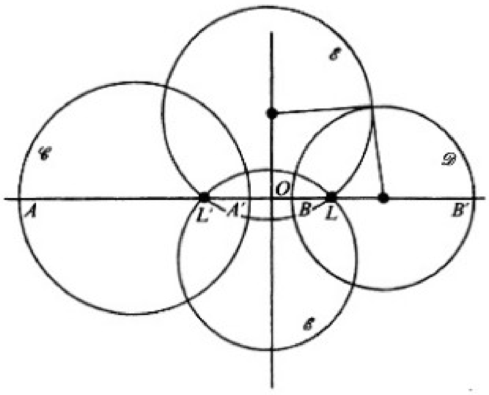

Fig. 25.1

The X–axis is the line of centers, and the Y–axis is a special line related to both circles called *the radical axis*. This line does not intersect either circle, as we see on putting $X = 0$ in both equations.

If $\mathscr{E}$ is the circle with equation

$$X^2 + Y^2 + 2kX+2/Y+c=0,$$

the orthogonality condition (Eqn (2), §22.1) applied to $\mathscr{E}$ and $\mathscr{C}$ and $\mathscr{E}$ and $\mathscr{D}$ is

$$2gk=p^2+c, 2g'k= p^2+c$$

Since $g \neq g'$, the circles $\mathscr{C}$ and $\mathscr{D}$ being distinct circles, we have $k = 0$, and $c = -p^2$. Hence the equation of $\mathscr{E}$ is

$$X^2 + Y^2 + 2lY - P^2 = 0$$

an equation in which l is the only variable parameter. This shows that a circle which cuts both $\mathscr{C}$ and $\mathscr{D}$ orthogonally must have its center on the radical axis (the Y–axis in this case) of the two circles, and such a circle cuts the line of centers, $Y = 0$, in the points given by $X^2 - p^2 = 0$, that is in the two fixed points $(p, 0)$ and $(-p, 0)$.

If we call these fixed points L and L', and the points where the line of centers cuts $\mathscr{C}$ and $\mathscr{D}$ respectively A, A' and B, B', we have

$$| OL | = | OL' |^2 = p^2 = \overline{OA} \,.\, \overline{OA'} = \overline{OB} \,.\, \overline{OB'},$$

since if we put $Y = 0$ in the equation of each circle we obtain the equations $X^2+2gX+p^2=0, X^2+2g^1X+p^2=0$,which show that $\overline{OA} \,.\, \overline{OA'} = p^2 = \overline{OB} \,.\, \overline{OB}$. From §19.1 it follows that L, L' are harmonic conjugates with respect to A, A' and to B, B'. Hence we have:

Corollary. Two non-overlapping pairs of points on a line have a pair of common harmonic conjugates.

This pair of common harmonic conjugates is unique. For if M, M' be another pair of harmonic conjugates to A, A' and B, B', and O' be the midpoint of MM', we should have $| O'M |^2 = | O'M' |^2 \ \overline{O'A} \,.\, \overline{O'A'} = \overline{O'B} \,.\, \overline{O'B'}$. and so the point O' would have the same *power* (§18.1) with respect to the circles $\mathscr{C}$ and $\mathscr{D}$. Such a point must lie on the radical axis of $\mathscr{C}$ and $\mathscr{D}$ (§27.3) and is therefore uniquely defined. Hence $O' = O$, and thence M, M' coincide with L, L'.

25.2 The inverse of a circle and a pair of inverse points

Theorem *If P and Q are points inverse in a circle $\mathscr{C}$, inversion in any circle center O maps P', Q' on points P', Q' inverse in the inverse $\mathscr{C}'$ of $\mathscr{C}$.*

Proof. All circles through P and Q are orthogonal to $\mathscr{C}$ (Thm 20.2). Hence after inversion all circles through P' and Q' are orthogonal to $\mathscr{C}'$. One such circle is the line $P'Q'$, the inverse of circle POQ. Hence $P'Q'$ is a diameter of $\mathscr{C}'$, and since circles through P' and Q' are orthogonal to $\mathscr{C}'$, the points P' and Q' are inverse points in $\mathscr{C}'$.

Remark. The proof holds with only minor modifications if $\mathscr{C}'$ is a line. Then P' and Q' are mirror images in the line.

Exercises

25.1 $\mathscr{C}$ is a circle which cuts a line l. From a point O on l a tangent OT is drawn to $\mathscr{C}$, and with center O and $|OT|$ as radius a circle is drawn which is orthogonal to $\mathscr{C}$. Show that this circle does *not* intersect the diameter of $\mathscr{C}$ which is perpendicular to l.

25.2 Let $\mathscr{C}$ and $\mathscr{D}$ be two circles which intersect in the points A and B. By inversion with respect to A as center show that the operations of inversion in distinct intersecting circles $\mathscr{C}$ and $\mathscr{D}$ are commutative if and only if $\mathscr{C}$ and $\mathscr{D}$ are orthogonal. (If inversion in $\mathscr{C}$ is represented by $\mathrm{T}^{\mathscr{C}}$, and in $\mathscr{D}$ by $T_{\mathscr{D}}$, we wish to show that if P is any point, $PT^{\mathscr{C}}T^{\mathscr{D}}=PT^{\mathscr{D}}T^{\mathscr{C}}$ if and only if $\mathscr{C}$ and $\mathscr{D}$ are orthogonal.)

25.3 Show that four mutually orthogonal circles can be inverted into a circle $\mathscr{C}$, two perpendicular diameters l and m of $\mathscr{C}$, and a concentric circle of radius r', where $r'^2 + r^2 = 0$, r being the radius of $\mathscr{C}$, so that this last circle is a virtual circle (§0.9). If the process of inversion in four mutually orthogonal circles be denoted by T_1, T_2, T_3, T_4, show that

$$P(T_1 T_2 T_3 T_4)=P,$$

for any point P. (This is the first encounter with inversion in a virtual circle, defined in §20.1.)

25.3 Circles into concentric circles

Theorem *Any two non-intersecting circles* $\mathscr{C}$ *and* $\mathscr{D}$ *may be inverted simultaneously into a pair of concentric circles*. (See Fig 25.2.)

Proof. By Thm 25.1 there exists a pair of points L, L' on the line of centers of $\mathscr{C}$ and $\mathscr{D}$ such that all circles orthogonal to $\mathscr{C}$ and to $\mathscr{D}$ pass through L and L', and, of course, such that all circles through L and L' are orthogonal to $\mathscr{C}$ and to $\mathscr{D}$. We invert with respect to one of these points, say L. Let L^* be the inverse of L'. Then since all circles through L and L' are orthogonal to $\mathscr{C}$ and to $\mathscr{D}$, all lines through L^* are orthogonal to $\mathscr{C}'$ and $\mathscr{D}'$, the inverses of $\mathscr{C}$ and of $\mathscr{D}$. Hence L^* is the common center of $\mathscr{C}'$ and $\mathscr{D}'$.

25.4 The Steiner porism

We are given two circles $\mathscr{C}$ and $\mathscr{D}$, one lying inside the other (Fig 25.3), and we begin to draw circles which touch both $\mathscr{C}$ and $\mathscr{D}$. Beginning with one such circle $\mathscr{C}_1$, the next circle we draw, $\mathscr{C}_2$, touches $\mathscr{C}$ and $\mathscr{D}$ and also $\mathscr{C}_1$. Then we draw $\mathscr{C}_3$ to touch $\mathscr{C}$ and $\mathscr{D}$ and $\mathscr{C}_2$, and so on, $\mathscr{C}\iota$ touching $\mathscr{C}$ and $\mathscr{D}$ and $\mathscr{C}_{i-1}$. We ask whether there exists a finite chain of circles $\mathscr{C}_1\mathscr{C}_2,\ldots\mathscr{C}_{n-1}\,\mathscr{C}_n$where each circle of the chain touches $\mathscr{C}$ and $\mathscr{D}$ and the two numerically adjacent circles, $\mathscr{C}\iota$ touching $\mathscr{C}_{i-1}$ and $\mathscr{C}_n$, and $\mathscr{C}_{n-1}$ itself touching $\mathscr{C}_{n-1}$ and $\mathscr{C}_1$?

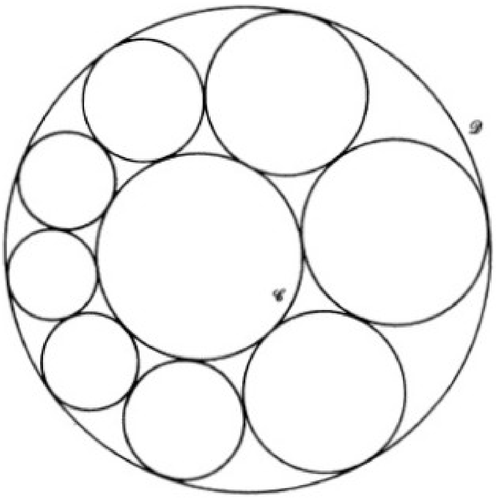

Fig. 25.3

If there is such a chain does it depend on where we start with $\mathscr{C}_1$, or may we draw $\mathscr{C}_1$ in any position, as long as it touches $\mathscr{C}$ and $\mathscr{D}$?

The answer to this problem is simple if we invert $\mathscr{C}$ and $\mathscr{D}$ into two concentric circles, which we may do by Thm 25.3, since they do not intersect. Our problem is reduced to the case when $\mathscr{C}'$ and $\mathscr{D}'$ are concentric. It is clear now that a chain only exists when there is a special relationship between *n* and the radii of $\mathscr{C}'$ and $\mathscr{D}'$, but that when this relationship *does* exist, since the whole configuration can be rotated about the common center of $\mathscr{C}'$ and $\mathscr{D}'$, it is independent of the position of the initial circle of the chain. Hence the problem of inscribing a chain of circles as described above has *no* solution or it has *an infinity* of solutions. This is why it is described as a porism. It was first formulated by Steiner.

25.5 The Steiner formula

It is of interest to obtain the formula given by Steiner which relates the radii of $\mathscr{C}$ and $\mathscr{D}$, the distance between their centers, and *n*, in the case when a chain of *n* circles can be inscribed to touch each other and $\mathscr{C}$ and $\mathscr{D}$.

Let us suppose that a common diameter of $\mathscr{C}$ and $\mathscr{D}$ intersects them in the points *A*, *B* and *C*, *D* respectively (Fig 25.4), and that after inversion with respect to *L*, which is a point on the common diameter, the points invert into A', B', and C', D', which will be the points of intersection of the same diameter with the concentric circles $\mathscr{C}'$ and $\mathscr{D}'$. Suppose that the radii of $\mathscr{C}$ and $\mathscr{D}$ are *R* and *r*, and the distance between their centers is *d*. Let the radii of the concentric circles $\mathscr{C}'$ and $\mathscr{D}'$ be R_1 and R_2. We use the result of §23.2, that $\{AB, CD\} = \{A'B', C'D'\}$, that is, that

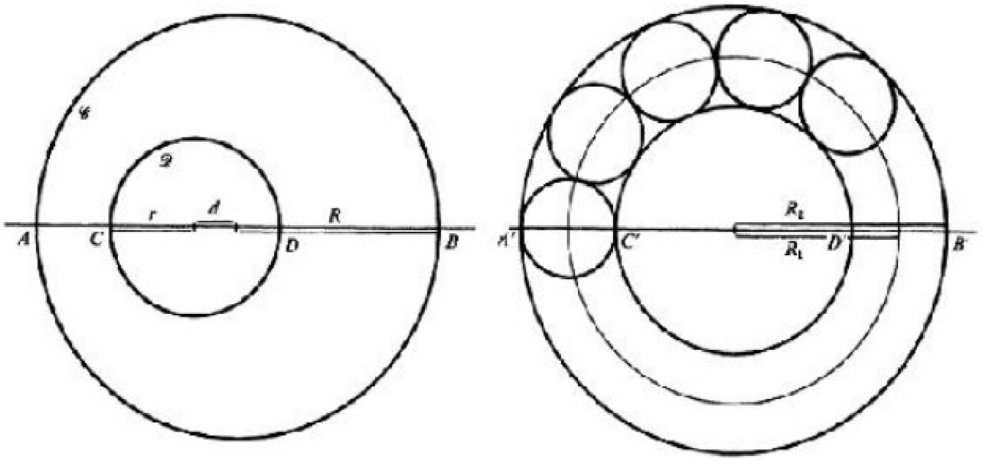

Fig. 25.4

$$\overline{AC}\,.\,\overline{BD}/\overline{AD}\,.\,\overline{BC} = \overline{A'C'}\,.\,\overline{B'D'}/\overline{A'D'}\,.\,\overline{B'C'}.$$

The left-hand side is readily seen to equal

$$(R-d-r)(R+d-r)/(R-d+r)=[(R-r)^2-d^2]/[(R+r)^2-d^2],$$

and the right-hand side is

$$(R_1-R_2)^2/R_1+R_2)^2$$

Equating these two expressions, a little reduction leads to

$$(R-r)^2-d^2=R_r(R_1/R_2/R_1-2).$$

Now if a chain of n circles can be inscribed to touch $\mathscr{C}'$ and $\mathscr{D}'$ (Fig 25.5), we have the simple relation

$$(R_2-R_2)/(R_2+R_1)=\sin(\pi/n),$$

so that

$$R_2/R_1=(1+\sin(\pi/n))/(1-\sin(\pi/n)),$$

and substitution gives us

$$(R-r)^2-d^2=4Rr\tan^2(\pi/n),$$

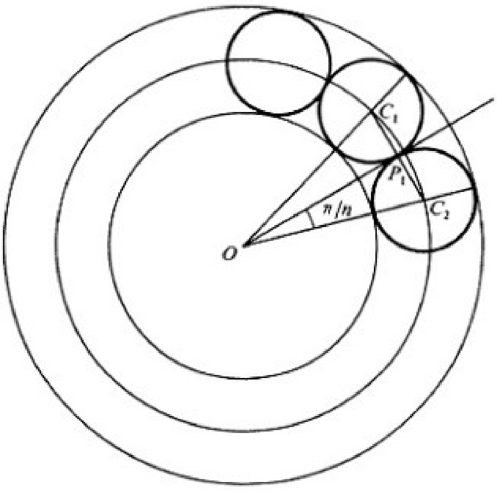

Fig. 25.5

for the relation between the radii of circles $\mathscr{C}$ and $\mathscr{D}$ and the distance between their centers which has to be satisfied for a chain of n circles to be inscribed, touching both circles.

Exercises

25.4 Show that two circles $\mathscr{C}$ and $\mathscr{D}$ intersecting at B and C are orthogonal if and only if there exist two circles touching $\mathscr{D}$ at B and C respectively which also touch each other at A, where A is any point on $\mathscr{C}$ distinct from B and C.

25.5 $\mathscr{C}$ and $\mathscr{D}$ are two distinct circles. Find the locus of a point P which is such that two circles, tangent both to $\mathscr{C}$ and $\mathscr{D}$ are also tangent to each other at P. (There are three cases to examine: $\mathscr{C}$ and $\mathscr{D}$ intersect: $\mathscr{C}$ and $\mathscr{D}$ touch, and $\mathscr{C}$ and $\mathscr{D}$ do not intersect.)

25.6 If the conditions for a chain of circles touching $\mathscr{C}$ and $\mathscr{D}$ are satisfied (The Steiner Porism, §25.4), show that the mutual points of contact of circles of the chain lie on a circle, and that this circle serves for inverting $\mathscr{C}$ into $\mathscr{D}$.

25.7 Continuing with Exercise 25.2, show that the operations of inversion in $\mathscr{C}$ and $\mathscr{D}$ cannot be commutative if $\mathscr{C}$ and $\mathscr{D}$ touch, or if $\mathscr{C}$ and $\mathscr{D}$ do not intersect.

26.1 The problem of Apollonius

Given three circles $\mathscr{C}_1\mathscr{C}_2$ and $\mathscr{C}_3$ how many circles can be drawn to touch all of them?

This is an example of a problem in which the variation or specialization of the given conditions (the circles in this case) may produce a change in the *number* of distinct solutions. A case encountered in the beginnings of Euclidean geometry is when the three circles are lines, and we consider how many circles can be drawn to touch the sides of a given triangle. There are *four* such circles, the incircle and the three excircles. Later we shall consider the matter algebraically (§38.1) and we shall see that the maximum *finite* number of solutions to the Apollonius problem is *eight*. Specialization of the circles to lines has halved the number of solutions.

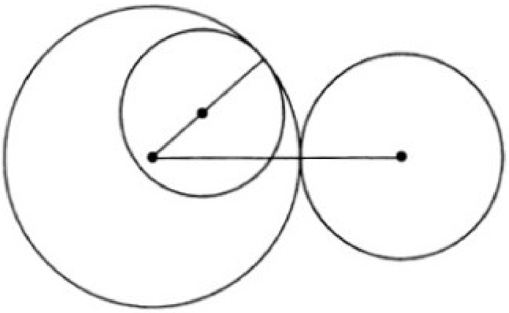

Fig. 26.1

In this section we shall examine the different possible cases of the Apollonius problem. If the circles $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$ are concentric, there are no real circles touching all three of them. We should stress, perhaps, that it is always *real* solutions we are seeking. (See §38.1.)

The condition for the contact of two circles can always be expressed thus:

(Distance between centers)= Sum or difference of radii,

according to the kind of contact, external or internal.

If the two circles be $\mathscr{C}$, $\mathscr{C}'$ (Fig 26.1), given in the usual form (§22.1), this condition becomes

$$(2gg'+2ff'-c-c')^2=4(g^2+f^2-c)(g'^2+f'^2-c'),$$

expressing the condition that if θ be the angle of intersection, $\cos\theta = \alpha 1$. Suppose now that the circle $\mathscr{C}'$ is a *point-circle*, that is a circle of zero radius, so that $g'^2 + f'^2 - c' = 0$. Then the condition for contact between $\mathscr{C}$ and a point-circle is

$$2gg'+2ff'-c-c'=0,$$

which is the condition that the point-circle itself, which is merely the point $(-g', -f')$, should lie on the circle $\mathscr{C}$, which is

$$g'^2+f'^2-2gg'-2ff'+c=0.$$

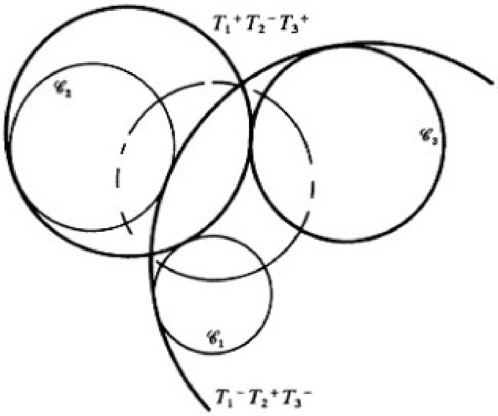

Fig. 26.2

This is a condition we could have reached intuitively, but it is satisfactory to have an algebraic verification. (In §37.1, we shall see that a similar result is true when a point-circle cuts another circle *orthogonally*.)

If the three given circles are each specialized to a point, the condition for a circle $\mathscr{C}$ to touch them is the condition that $\mathscr{C}$ should pass through the three given points. There is only one circle through three points, so we have a case when there is only *one* solution to the problem of Apollonius.

We shall set some special cases, which yield two, three, four, five and six solutions, as Exercises. In the meantime let us see why the number *eight* appears to be the correct number of solutions when the given circles are not specialized. We assume that there is at least one circle which touches the three given circles. Now suppose that we denote a circle (Fig 26.2) which touches $\mathscr{C}_1$ externally by the symbol T_1^+, and one which touches $\mathscr{C}_1$ internally by the symbol T_1^-. Then a combination of the three symbols such as

$$T_1^+T_2^-T_3^+$$

describes a circle which touches $\mathscr{C}_1$ externally, $\mathscr{C}_2$ internally, and $\mathscr{C}_3$ externally. There are *eight* combinations of a triad of plus or minus symbols, namely + + +,

+ + –, + – –, +– +, –++, – +–, – – –, – – +, and therefore if there is a unique circle which corresponds to a triad of the symbols (for instance, a unique circle which touches all of the given circles externally), we expect a total of eight contact circles in all, since there seems no reason, if the circles are not specialized, for one kind of contact to be favoured more than another.

This sounds a rather unmathematical argument, but it can be made to depend on mathematical reasoning. We observe that the distinction between external and internal contact of a circle $\mathscr{C}$ with $\mathscr{C}_1$ vanishes if $\mathscr{C}_1$ becomes a point circle, and we expect, if our reasoning has anything in it, that there are only four circles which pass through a point and touch two given circles $\mathscr{C}_3$ and $\mathscr{C}_3$. In fact, inversion with respect to the point $\mathscr{C}_1$ shows this at once, since the circles $\mathscr{C}_{2'}$ and $\mathscr{C}_{3'}$ have four common tangents, and these arise from the circles through $\mathscr{C}_1$ which touch $\mathscr{C}_2$ and $\mathscr{C}_3$.

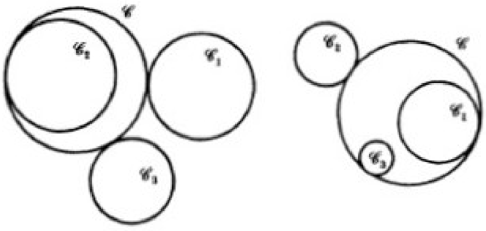

Fig. 26.3

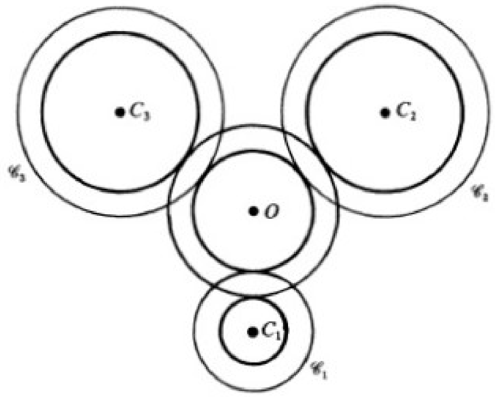

Fig. 26.4

We may think that the case in which $\mathscr{C}_1$ $\mathscr{C}_2$ and $\mathscr{C}_3$ all lie outside each other is more general than the case when, say, $\mathscr{C}_2$ and $\mathscr{C}_3$ lie inside $\mathscr{C}_1$. But if we invert with respect to $\mathscr{C}_1$ this goes into itself, and if $\mathscr{C}_2$ and $\mathscr{C}_3$ lie outside $\mathscr{C}_1$ they invert into circles inside $\mathscr{C}_1$. Again, if we have a circle $\mathscr{C}$ (Fig 26.3) which touches $\mathscr{C}_1$ externally, $\mathscr{C}_2$ internally, and $\mathscr{C}_3$ externally, and we invert with respect to $\mathscr{C}$, the case $T_1^+T_2^-T_3^+$ does turn into $T_1^-T_2^+T_3^-$, since $\mathscr{C}$ inverts into itself, and $\mathscr{C}_1$ which lies outside $\mathscr{C}$, inverts into a circle inside $\mathscr{C}$ the circle $\mathscr{C}_2$ which lies inside $\mathscr{C}$ inverts into a circle outside $\mathscr{C}$ and $\mathscr{C}_3$ which lies outside $\mathscr{C}$ inverts into a circle inside $\mathscr{C}$. Hence if we can show that there is one circle which satisfies the condition $T_1^+T_2^+T_3^+$, and one which satisfies, say, the condition $T_1^-T_2^+T_3^+$, inversions will prove that circles satisfying the other six conditions exist, since we may evidently permute the numbers 1, 2 and 3 in these considerations. (As soon as we have established the existence of a circle Σ orthogonal to $\mathscr{C}_1$,$\mathscr{C}_2$ and $\mathscr{C}_3$ (§28.2), inversion in Σ maps each $\mathscr{C}_1$ onto itself, and can interchange the signs for any given circle condition, but see the remark below.)

We choose our circles $\mathscr{C}_1$,$\mathscr{C}_2$ and $\mathscr{C}_3$ (Fig 26.4) so that the radii of $\mathscr{C}_2$ and $\mathscr{C}_3$ are equal, and so that the center of $\mathscr{C}_1$ is equidistant from the centers of $\mathscr{C}_2$ and $\mathscr{C}_3$. We also choose the radius of $\mathscr{C}_1$ to be less than that of $\mathscr{C}_2$ or $\mathscr{C}_3$. If there is a circle $\mathscr{C}$ of center O which touches the three given circles externally, decreasing the radii of the three circles by the same amount enables us to construct a circle center O which still touches the diminished circles externally. All we have to do is to increase the radius of $\mathscr{C}$ by the amount the other three radii are decreased.

Eventually we arrive at a point circle center C_1, and two equal circles centers C_2 and C_3. If we can draw a circle through C_1 to touch the equal circles centers C_2 and C_3 externally, then we can move back to the circle touching the three original circles externally. If there is only one such circle, we may argue that in a more general case there is only one. We naturally invert with respect to C_1 (Fig 26.5), but we choose as circle of inversion the circle center C_1 which is orthogonal to both circles $\mathscr{C}_2$ and $\mathscr{C}_3$. Since their centers are at equal distances from C_1, and their radii are equal, this is possible. After inversion therefore, the circles centers C_2 and C_3 are unchanged, but the circle through C_1 which touches them has inverted into a common tangent. It is clear that it is the external common tangent shown, the other common tangents inverting into circles through C_1 which do not have external contact with both of the circles $\mathscr{C}_2$ and $\mathscr{C}_3$.

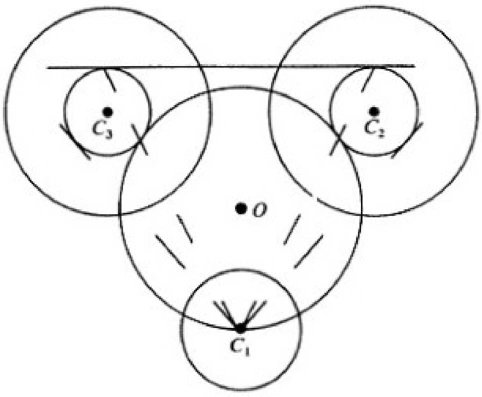

Fig. 26.5

To show that there is one circle satisfying the condition $T_1^-T_2^+T_3^+$ is left as an Exercise.

Remark. Nothing in the above discussion indicates that the eight circles which touch three given circles *always* conform to the pattern we have described. For example, if the centers of $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$ are collinear, the circle orthogonal to the three circles is the line of centers, and inversion in this circle is equivalent to reflexion in the line. It is clear that if there is a $T_1^+T_2^+T_3^+$ contact circle, reflexion in the line of centers produces another contact circle *of the same type*, and similarly all existing types of contact circles occur in pairs. What we have shown above is that there is a case (or there are cases) where our heuristic argument is valid.

Exercises

26.1 Show that a variation of the method given above enables us to assert that there is a unique circle satisfying the condition $T_1^-T_2^+T_3^+$.

26.2 Discuss the types of contact circle given by the other common tangents to the reduced circles $\mathscr{C}_2$ and $\mathscr{C}_3$ in the method for finding a circle with three external contacts described above. In combination with the method of the first Exercise above, are all the eight contact circles produced by the two methods?

26.3 $\mathscr{C}_1$ and $\mathscr{C}_2$ are point-circles, and $\mathscr{C}_3$ is a proper circle. Show that there are two contact circles, touching all three circles.

26.4 $\mathscr{C}_1$ is a point-circle, and $\mathscr{C}_2$ and $\mathscr{C}_3$ are proper circles which touch each other. Show there are three solutions to the problem of Apollonius.

26.5 $\mathscr{C}_1$ and $\mathscr{C}_2$ are proper circles, and $\mathscr{C}_3$ touches both $\mathscr{C}_2$ and $\mathscr{C}_3$ but these latter circles do not touch. Show there are four solutions to the Apollonian problem, or five if we count $\mathscr{C}_1$ in the solutions.

26.6 $\mathscr{C}_1$ and $\mathscr{C}_2$ all touch each other. Show that there are two circles distinct from the given ones which touch the three circles, so that, since each of the given circles is a solution of the problem, there are five solutions in all.

26.7 $\mathscr{C}_1$ and $\mathscr{C}_2$ touch, and $\mathscr{C}_3$ is a proper circle which does not touch $\mathscr{C}_1$ or $\mathscr{C}_2$. Show that there are six distinct circles which touch the three given circles.

†**26.8** Can you find a case when there are seven distinct solutions? (None of the many papers on the problem of Apollonius mentions this case specifically. Can you prove that such a case is impossible?)

26.9 If $\mathscr{C}_1$ contains both $\mathscr{C}_2$ and $\mathscr{C}_3$ discuss the possible types for the eight contact circles.

26.10 l and m are two parallel tangents to a circle $\mathscr{C}$ and a further tangent n intersects l in P and m in Q. Prove that the circle on PQ as diameter contains the center of $\mathscr{C}$.

Deduce by inversion that if three equal circles $\mathscr{C}_1, \mathscr{C}_2$ and $\mathscr{C}_3$ pass through the same point O, $\mathscr{C}_1$ and $\mathscr{C}_2$ touching at O, then if $\mathscr{C}_1$ intersects $\mathscr{C}_3$ again at P, and $\mathscr{C}_2$ intersects $\mathscr{C}_3$ again at Q, PQ is a diameter of $\mathscr{C}_3$. (There is also a more direct and simple proof.)

---

† See Pedoe, D., '*The Missing Seventh Circle', Elemente der Mathematik*, **25**, Jan. 1970, p. 14–15.

Since

$$L_{12} + L_{23} \equiv C_1 - C_3 = 0 \equiv L_{13}$$

the radical axis L_{13} of $\mathscr{C}_1$ and $\mathscr{C}_3$ passes through the intersection of L_{12} and L_{23}, if they have an intersection, or L_{13} is parallel to both lines, if they are parallel.

28.2 The circle orthogonal to three given circles

The theorem of the preceding Section shows us that there is at least one point, finite or at infinity, which has the same power with respect to three given circles $\mathscr{C}_1$ $\mathscr{C}_2$ $\mathscr{C}_3$(Fig. 28.2). If the three circles belong to the same coaxal system, every point on the common radical axis has this property. If the circles are not in the same coaxal system there is a unique point with this property. It is called *the radical center* of the three circles. If it lies outside one, and therefore each of the three circles, and the point be designated as V, and the common power as $|VT|^2$, a circle radius $|VT|$ and center V will cut each of the three circles $\mathscr{C}_i$ orthogonally. If the radical center lies inside one of the circles, and therefore inside each of them, and the common power is $-|VT|^2$, the common orthogonal circle is a *virtual* circle, with equation

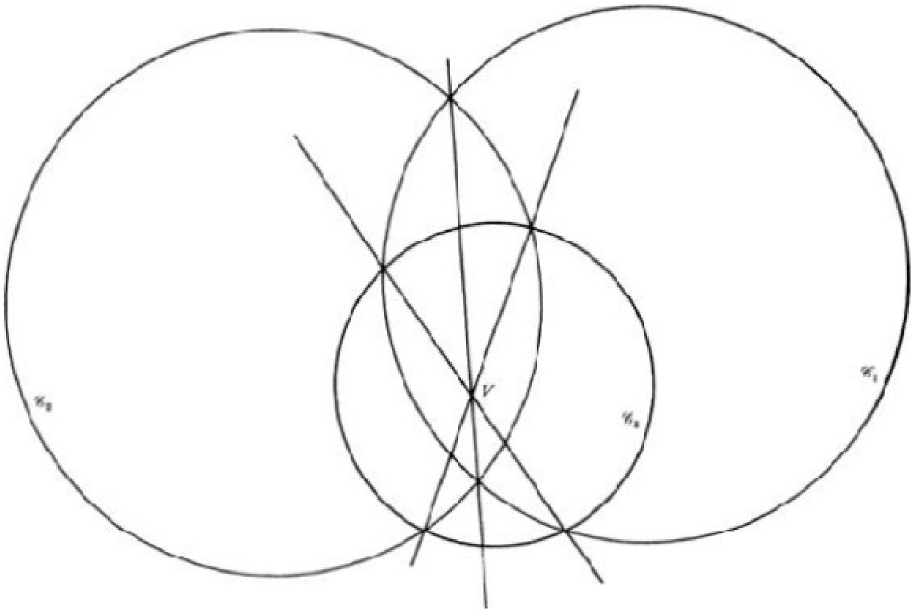

Fig. 28.2

$$(X-a)^2+(Y-b)^2+r^2=0,$$

where $r^2=|VT|^2$, and the coordinates of V are (a, b). Algebraically, this virtual circle satisfies the condition for orthogonality with each of the circles $\mathscr{C}_i$.

The common orthogonal circle, if taken as circle of inversion, inverts each circle $\mathscr{C}_i$ into itself, and, in particular, inverts any circle $\mathscr{C}$ which touches the three circles into a distinct circle $\mathscr{C}'$ which touches the three circles. We assume that $\mathscr{C}$ is not also orthogonal to the common orthogonal circle. Hence we expect the circles which touch the three given circles to fall into pairs, mutually inverse in the common orthogonal circle. (See §26.1 and §38.1.) The consideration of inversion in a virtual circle arises quite naturally in this context.

When the centers of the three circles $\mathscr{C}_i$ are collinear, the common orthogonal circle is a line, the line of centers, and the radical center is at infinity. Inversion in the common orthogonal circle is reflexion in the line of centers in this case.

Exercises

28.1 If $\mathscr{C}_1$, $\mathscr{C}_2$ are two non-intersecting circles, and $\mathscr{C}_3$ intersects $\mathscr{C}_1$ in the points P, Q and $\mathscr{C}_2$ in the points R, S, prove that the point $PQ \cap RS$ lies on the radical axis of $\mathscr{C}_1$ and $\mathscr{C}_2$.

28.2 A circle drawn through two given points P, P' intersects a given circle $\mathscr{C}$ in the points Q and R. Prove that the lines QR form a pencil, that is, they either all pass through a point, or they are all parallel to each other. Hence prove that two circles through P and P' touch $\mathscr{C}$, and show how to construct them.

28.3 Prove the following construction, due to Gergonne, for a circle which touches three given circles $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$. Draw the circle which is orthogonal to the three given circles. (See §28.2.) Draw the three chords of intersection of this circle with $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$ respectively. From the points where these chords meet an axis of similitude of the three circles $\mathscr{C}_1$, $\mathscr{C}_2$, $\mathscr{C}_3$ (See Exercise 13.2) draw pairs of tangents to $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$. Then the two circles drawn through these six points of contact will touch $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$. (We shall see later, in §38.1, an algebraic verification of the theorem that the circles touching three given circles $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$ are inverse in pairs in the common orthogonal circle of the three given circles. But since circles are invariant under inversion in a circle orthogonal to them, the circles $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$ invert into themselves under inversion in their common orthogonal circle, and a circle which touches them at A, B and C say inverts into a circle which touches them at A', B' and C', where the primes denote points inverse to A, B and C in the common orthogonal circle. Hence circle ABC, the orthogonal circle, and circle $A'B'C'$ are in a coaxal system (Exercise 21.6). Therefore, by Thm 28.1, the radical axes of $\mathscr{C}_1$ and each of the three coaxal circles we are discussing meet in a point. Two of the radical axes are tangents at A and A' to $\mathscr{C}_1$, and the third is the common chord of $\mathscr{C}_1$ and the common orthogonal circle. Finally, if P is the point of intersection of these three lines, P must be on an axis of similitude (See Exercise 13.2) of the three given circles, because $|PA| = |PA'|$ shows that P lies on the radical axis of circles ABC, $A'B'C'$, and by Exercise 18.3 we know that if two circles touch two others tdical axis of either pair passes through a center of similitude of the other pair, and since circles ABC, $A'B'C'$ touch $\mathscr{C}_1$, $\mathscr{C}_2$and $\mathscr{C}_3$, the radical axis of the two touching circles passes through three centers of similitude: it is an axis of similitude of $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$

28.4 Since three circles have four axes of similitude, the above construction yields eight Apollonian circles (compare §26.1). Draw them.

28.3 Another proof of the nine-point circle theorem

In §12.1 we saw that if A, B and C are the vertices of a triangle, D', E' and F' the feet of the perpendiculars from the vertices onto the opposite sides, and α, β, γ the midpoints of BC, CA and AB respectively, then there is a circle which passes through these six points and also the three midpoints of HA, HB and HC, where H is the orthocenter, the intersection of AD', BE' and CF' (Fig. 28.3). We remark that $|CD'|.|CB| = |CE'| . |CA|$, since a circle on AB as diameter passes through D' and E'. We deduce that $|C\alpha| . |CD'| = |C\beta| . |CE'|$, by halving each side of the equation. Hence the points α, D', β and E' are concyclic. Let them lie on a circle $\mathscr{C}_3$. Similarly the points α, D', γ, F' are concyclic. Let them lie on a circle $\mathscr{C}_2$. If the circles $\mathscr{C}_3$ and $\mathscr{C}_2$ do not coincide, they have the chord of intersection $\alpha D'$, which is the line BC. The points γ, F', β, E' are concyclic. Let them lie on a circle $\mathscr{C}_1$. If $\mathscr{C}_1 \neq \mathscr{C}_2$, their chord of intersection is AB, and if $\mathscr{C}_1 \neq \mathscr{C}_3$, their chord of intersection is AC. Hence, if the circles $\mathscr{C}_1$, $\mathscr{C}_2$and $\mathscr{C}_3$ are distinct, their radical axes, taking the circles in pairs, form the sides of a triangle. This contradicts Thm 28.1. Hence the points α, β, γ, D', E' and F' all lie on one circle. As in §12.1, by applying this result to the triangle BHC, we show that this circle also contains the midpoints of HA, HB and HC.

touching circles passes through three centers of similitude: it is an axis of similitude of $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$

28.4 Since three circles have four axes of similitude, the above construction yields eight Apollonian circles (compare §26.1). Draw them.

28.3 Another proof of the nine-point circle theorem

In §12.1 we saw that if A, B and C are the vertices of a triangle, D', E' and F' the feet of the perpendiculars from the vertices onto the opposite sides, and α, β, γ the midpoints of BC, CA and AB respectively, then there is a circle which passes through these six points and also the three midpoints of HA, HB and HC, where H is the orthocenter, the intersection of AD', BE' and CF' (Fig. 28.3). We remark that $|CD'|.|CB| = |CE'| \,.\, |CA|$, since a circle on AB as diameter passes through D' and E'. We deduce that $|C\alpha| \,.\, |CD'| = |C\beta| \,.\, |CE'|$, by halving each side of the equation. Hence the points α, D', β and E' are concyclic. Let them lie on a circle $\mathscr{C}_3$. Similarly the points α, D', γ, F' are concyclic. Let them lie on a circle $\mathscr{C}_2$. If the circles $\mathscr{C}_3$ and $\mathscr{C}_2$ do not coincide, they have the chord of intersection $\alpha D'$, which is the line BC. The points γ, F', β, E' are concyclic. Let them lie on a circle $\mathscr{C}_1$. If $\mathscr{C}_1 \neq \mathscr{C}_2$, their chord of intersection is AB, and if $\mathscr{C}_1 \neq \mathscr{C}_3$, their chord of intersection is AC. Hence, if the circles $\mathscr{C}_1$, $\mathscr{C}_2$and $\mathscr{C}_3$ are distinct, their radical axes, taking the circles in pairs, form the sides of a triangle. This contradicts Thm 28.1. Hence the points α, β, γ, D', E' and F' all lie on one circle. As in §12.1, by applying this result to the triangle BHC, we show that this circle also contains the midpoints of HA, HB and HC.

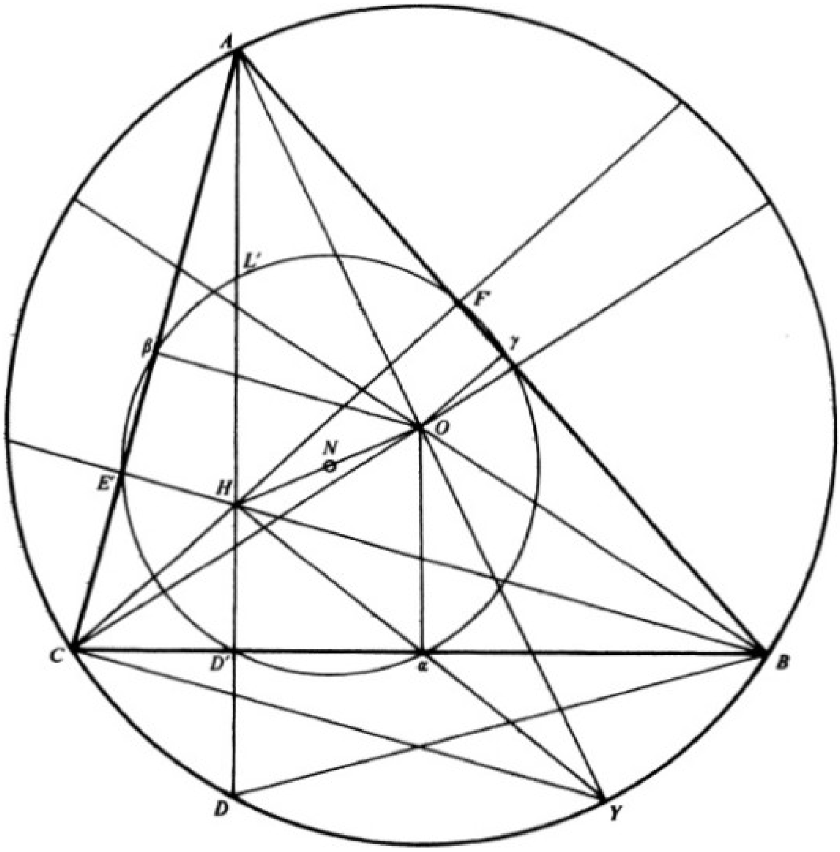

Fig. 28.3

28.4 Clerk Maxwell's derivation of reciprocal figures

We use the notation of §6.1. Let ABC be a triangle, and D a point not on the sides. The triangle PQR is such that QR is parallel to DA, RP is parallel to DB and PQ is parallel to DC. We wish to show the existence of a point F such that BC is parallel to FP, CA is parallel to FQ and AB is parallel to FR.

Maxwell, who was a geometer as well as a great physicist, drew circles with centers at the points A, B, C and D respectively (Fig. 28.4), and remarked that the chord of intersection of each pair of circles is perpendicular to the line joining the centers, and that the chords of intersection of the pairs which can be taken from three circles pass through one point (Thm 28.1). Hence the four

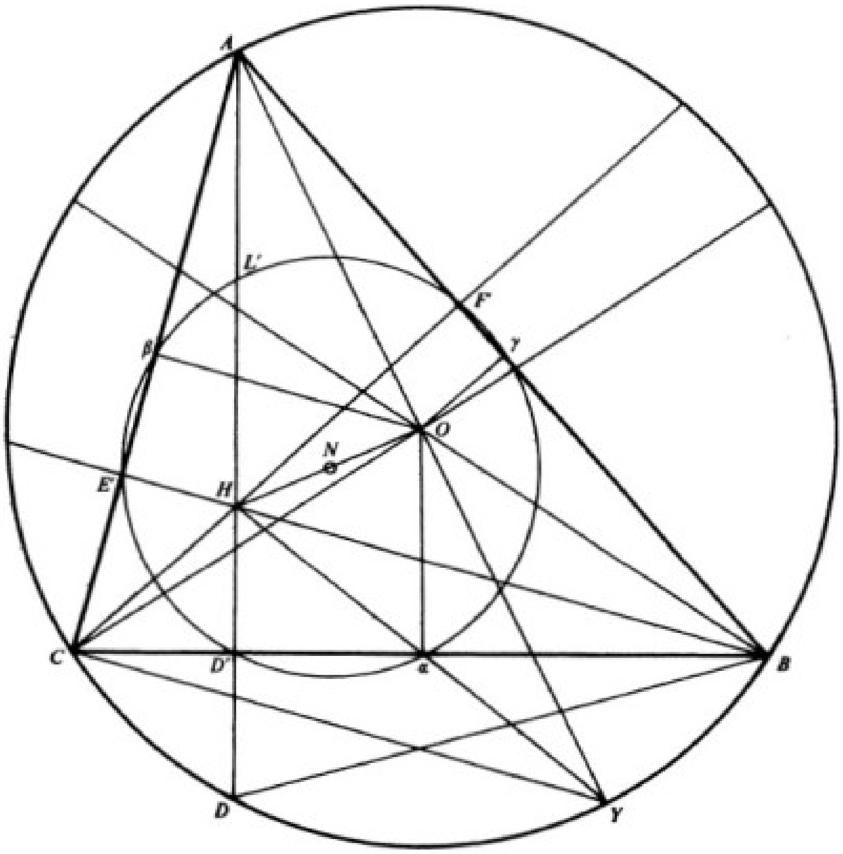

Fig. 28.3

28.4 Clerk Maxwell's derivation of reciprocal figures

We use the notation of §6.1. Let ABC be a triangle, and D a point not on the sides. The triangle PQR is such that QR is parallel to DA, RP is parallel to DB and PQ is parallel to DC. We wish to show the existence of a point F such that BC is parallel to FP, CA is parallel to FQ and AB is parallel to FR.

Maxwell, who was a geometer as well as a great physicist, drew circles with centers at the points A, B, C and D respectively (Fig. 28.4), and remarked that the chord of intersection of each pair of circles is perpendicular to the line joining the centers, and that the chords of intersection of the pairs which can be taken from three circles pass through one point (Thm 28.1). Hence the four circles constructed have common chords which pass in threes through four points *A'*, *B'*, *C'* and *D'*, where *B'C'* is perpendicular to *DA*, *C'A'* is perpendicular to *DB*, *A'B'* is perpendicular to *DC*, and *D'A'* is perpendicular to *BC*, *D'B'* is perpendicular to *CA* and *D'C'* is perpendicular to *AB*.

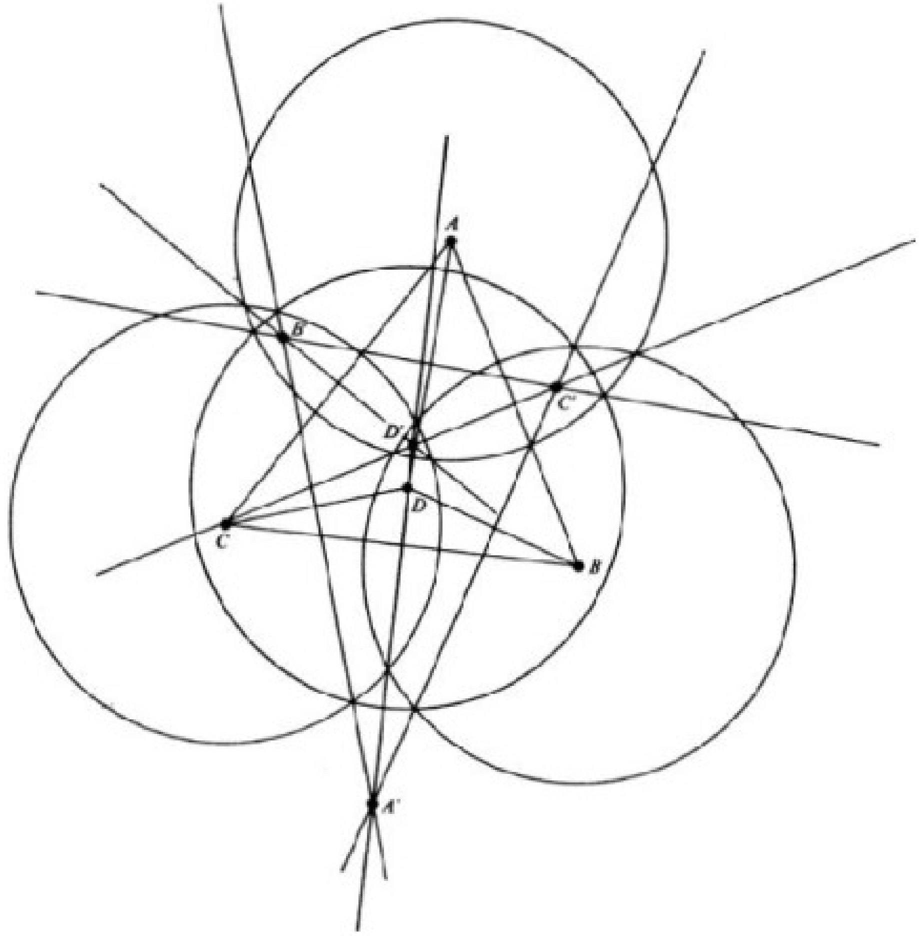

Fig. 28.4

If we now rotate the figure *A'B'C'D'* through a right angle, the figure reciprocal to *ABCD* is in existence! The triangle *A'B'C'* is similar to the given triangle *PQR*, and the point *F* is immediately obtained from the point *D'* which corresponds to it in triangle *A'B'C'*. Through *P* we draw a line parallel to *BC*, and through *Q* a line parallel to *CA*. The intersection *F* of these two lines will be such that *FR* is parallel to *AB*.

MAPPINGS OF THE EUCLIDEAN PLANE

In this chapter we propose to investigate the fundamental bijective (one-to-one onto) mappings of the Euclidean plane, using algebraic methods, and, in particular, complex numbers. Some of these mappings have already appeared in purely geometric guise (§12.1, §14.1). Some of the proofs given previously may seem to depend on the acceptance of the correctness of diagrams, and it is important to show that algebraic proofs are also possible. The algebra of complex numbers is very useful in this connection, but we shall try not to lose sight of the geometrical meaning of theorems and, in fact, it will be evident in many cases that the algebra is motivated by the geometry.

In §0.4 we gave the properties of complex numbers which we shall be using. We saw that we may regard the Euclidean plane as a representative of the field of complex numbers, the point (a, b) being associated with the complex number $a + ib$. When the Euclidean plane is regarded in this way we shall refer to it as *the Gauss plane*. Complex numbers will be denoted by lower-case letters, such as z, a, b, etc., and although we have just mapped the point (a, b), where a, b are real numbers, onto the complex number $z = a + ib$, there will be no misunderstanding if we talk of the mapping $z' = az$, where $|a| = 1$, it being understood that a is a complex number in this case. We shall naturally talk of ‘the point z' instead of ‘the point of the Euclidean plane associated with the complex number z'.

41.1 Translations

Let b be a fixed complex number, and consider the mapping

$$z' = z + b.$$

It is clear that every point z is moved through a fixed distance and in a fixed direction, given by the complex number b regarded as a vector. Such a mapping is called a *translation* (see Fig. 41.1). If $b = 0$, the mapping is the identity mapping.

41.2 Rotations

The mapping $z' = (\cos\varphi + i\sin\varphi)z$, leaves the modulus of z unchanged, but increases its amplitude by φ, and therefore moves the point representing z around the circle, center at the origin, which passes through the point z, and through a fixed angle φ. This is *a rotation about the origin* (see Fig. 41.2).

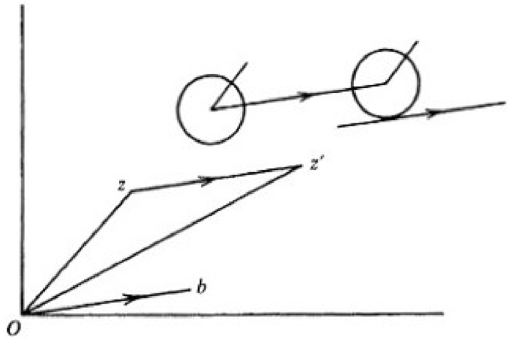

Fig. 41.1

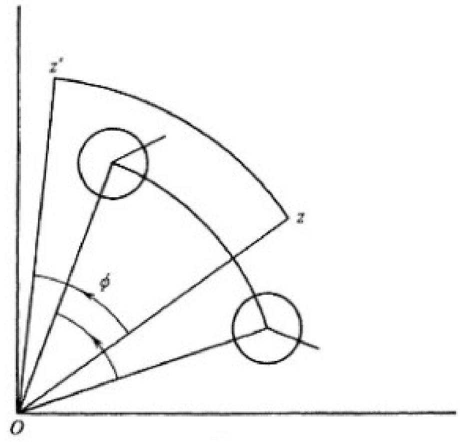

Fig. 41.2

This mapping may also be written $z' = az$, where $|a| = 1$, so that $a = \cos\varphi + i\sin\varphi$. If $a = 1$, we obtain the identity mapping.

41.3 Reflexions

The mapping $z' = \bar{z}$ is a reflexion in the X_1-axis (Fig. 41.3). If we require a reflexion in the line which passes through the origin, and makes an angle α with the X_1-axis, it is given by $z' = (\cos 2\alpha + i \sin 2\alpha)\bar{z}$, since we have at once $|z| = |z'|$, and $am\, z' + am\, z = 2\alpha$, so that the given line always bisects the angle between the joins of the origin to the points z and z'. The difference between the mappings when the map is a rotation and when it is a reflexion should be noted.

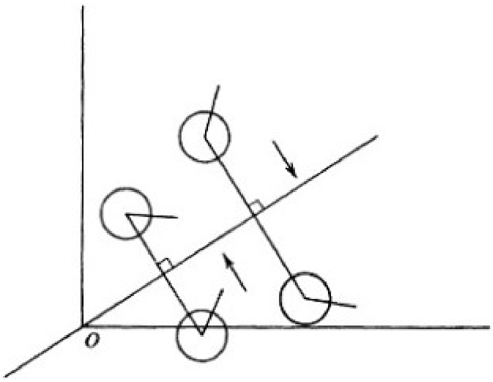

Fig. 41.3

41.4 Inversion

This is not a mapping of the Gauss plane, but of the plane with the center of inversion removed (Fig. 41.4). We shall overcome this difficulty in the next chapter, but in the meantime we remark that $z' = 1/z$ is equivalent to inversion in the unit circle, center at the origin, followed by reflexion in the X_1-axis. For if $z = r(\cos \theta + i \sin \theta), z^{-1} = r^{-1}(\cos (-\theta) + i \sin (-\theta))$, and the inverse of z is the point $r^{-1}(\cos (\theta) + i \sin (\theta))$. If we wish to obtain the inverse of z directly, we write $z' = 1/\bar{z}$.

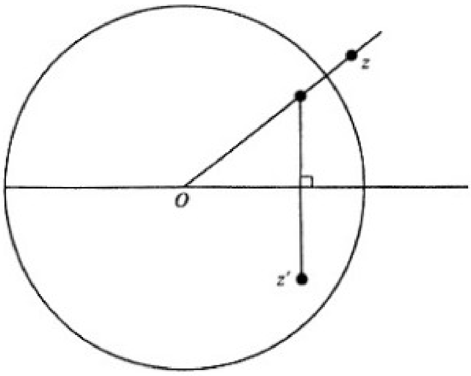

Fig. 41.4

41.5 Central dilatations

We can combine mappings (Fig. 41.5). Let us consider the mapping $z' = az$, where

$$a = |a|(\cos \alpha + i \sin \alpha).$$

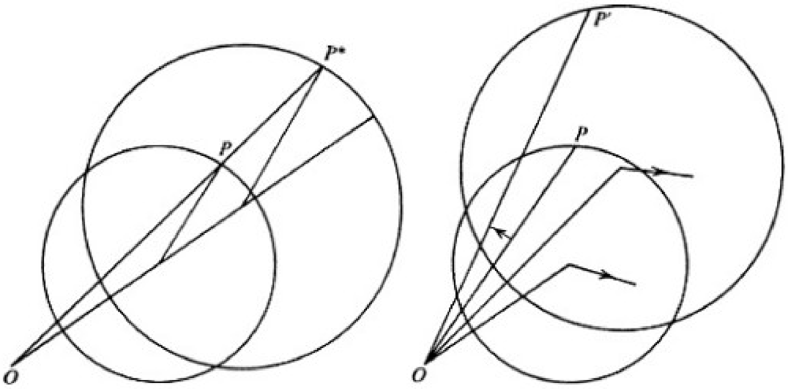

Fig. 41.5

Then $z = r(\cos \theta + i \sin \theta)$ is mapped on

$$z' = |a|r(\cos(\theta + \alpha) + i\sin(\theta + \alpha)).$$

The point P representing z is stretched to the point P^*, where $\overline{OP^*} = |a|\overline{OP}$, (that is, stretched in a fixed ratio), and OP^* is then rotated about O through the fixed angle α to OP', where P' represents z'.

We note that the order in which the two operations, stretching and rotation, are carried out does not affect the final result. That is, they are *commutative* operations. If a is real, so that $\alpha = 0$, the mapping is called either a *central similarity*, or a *central dilatation*, or merely a *magnification* or *enlargement*, but if rotation is also involved, it is called a *dilative rotation* about O, or a *spiral similarity*. Each of these terms is fairly easy to remember. We encountered central dilatations in §12.1, reflexions in a line in §14.1, rotations in the same section, and inversions in §20.1. Translations, of course, are implicit in the equivalence relation defined for vectors in §1.1. A free vector is obtained from a bound vector by means of a translation.

All of the mappings mentioned above can be used to solve certain types of geometrical problem. We have already seen the power of inversion in the § 20.1–onwards, and we have used reflexions to solve certain problems and to prove special theorems. The Exercises below can be solved by the use of the mappings we have discussed. We omit Exercises which need inversion.

Exercises

41.1 Two circles $\mathscr{C}_1$ and $\mathscr{C}_2$ are given, and a line l. Find a point A on $\mathscr{C}_1$ and a point B on $\mathscr{C}_2$ such that AB is parallel to l, and the distance $AB = d$, where d is given. (What is the map of a given circle under a translation?)

41.2 Two circles $\mathscr{C}_1$ and $\mathscr{C}_2$ are given, and a line l. Construct squares $ABCD$ with A and C on l, with B on $\mathscr{C}_1$, and D on $\mathscr{C}_2$. (What is the reflexion of a given circle in a given line?)

41.3 Show how to construct an equilateral triangle which has one vertex at a given point A, and one vertex on each of two given lines l and m. (What locus do we obtain if we rotate a given line through a given angle A about a given point?)

41.4 A point A and lines l and m are given. Show how to construct a square $ABCD$, with vertex A at A, vertex B on l, and vertex C on m. (What is the locus of l under the spiral similarity, center A, given by the equation $z' = az$, where $|a| = \sqrt{2}\,1$ and $am\ a = + \pi/4$, or $- \pi/4$?)

41.5 Show that a central dilatation, $z' = pz$, where p is real, maps a line onto a parallel line. Show also that if $z'' = qz'$ be another central dilatation with the same center, this maps the point z' onto the point $z'' = qpz$. Show that if the two mappings be combined, with the second first, we obtain $z'' = pqz$ as a result of the composition, so that the final result is independent of the order in which the mappings are combined. Use this result to obtain the parallel case of the Pappus Theorem of §9.5. (The points A, B, C lie on l, and the points A', B', C' lie on m. Given that AC' is parallel to CA', and CB' is parallel to BC', we wish to prove that AB' is parallel to BA'. Use central dilatations with center at $l \cap m$. Let $C = AT_1$, so that $A' = C'T_1$, and let $B = CT_2$, so that $C' = B'T_2$. Show that $B = AT_1T_2$, and $A' = B'T_2T_1$. From $T_1T_2 = T_2T_1$, deduce the theorem.)

42.1 Isometries

We note that the mappings: *translation*, *rotation* and *reflexion*, are all such that the distance between two points is unchanged by one of these mappings. If the two points are z and w, a translation gives

$$|z' - w'| = z + b - (w + b)| = |z - w|,$$

a rotation gives and reflexion in a line through the origin, which we can write $z' = a^{\bar{z}}$, where $|a| = 1$, gives so that our assertion is proved in all three cases.

$$\begin{aligned} |z' - w'| &= |(\cos\varphi + i\sin\varphi)z - (\cos\varphi + i\sin\varphi)w| \\ &= |(\cos\varphi + i\sin\varphi)||(z - w)| = |z - w|, \end{aligned}$$

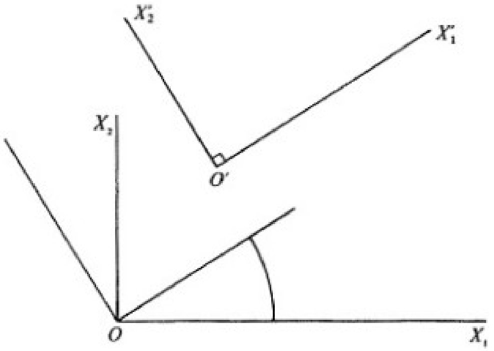

Fig. 42.1

$$|z' - w'| = |a\overline{(z - w)}| = |z - w|,$$

We know that inversion and central dilatations do change the distance between a pair of points.

Definition. An *isometry* of the Gauss plane is a one-to-one onto mapping of the plane such that if P is mapped on P' and Q is mapped on Q', the distance PQ = distance $P'Q'$, whatever the points P and Q.

Such mappings are also called *congruent transformations*, or *rigid motions*. The mappings: *translation*, *rotation* and *reflexion* are all isometries, and compositions of them are naturally also isometries. Two important ones must be familiar to the reader.

42.2 Coordinate transformations

We assume that our coordinate axes are orthogonal cartesian, and we *rotate* them through an angle φ about the origin, and in a positive direction, from the

X_1-axis towards the X_2-axis (Fig. 42.1).

We then *translate* the new position of the axes so that the original origin O falls on the point $O' = b$, where b is a complex number referred to the original axes. Calling the original axes OX_1, OX_2, call the new position of the axes $O'X_1'$, $O'X_2'$.

After the rotation the point which was originally z with respect to the original axes has become

$$z(\cos(-\varphi) + i\sin(-\varphi))$$

with respect to the axes rotated through φ about O, and the point b has become $b(\cos(-\varphi) + i\sin(-\varphi))$ with respect to these axes. After the translation, the point z becomes, with respect to the axes $O'X_1'$, $O'X_2'$:

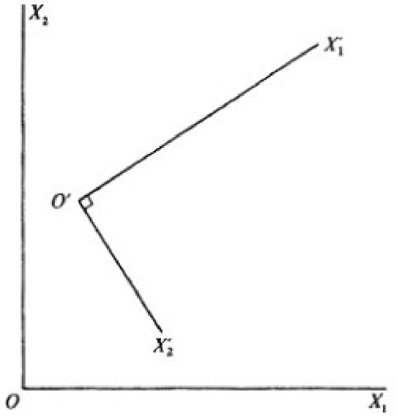

Fig. 42.2

$$Z' = z(\cos(-\varphi) + i\sin(-\varphi)) - b(\cos(-\varphi) + i\sin(-\varphi)),$$

which we may write

$$Z' = az + c, \text{ where } |a| = 1.$$

The same point now has two different names, or aliases: z with respect to the original axes, and $Z' = az + c$ with respect to the new axes.

If we suppose that the coordinate axes remain unchanged, and consider the mapping $Z' = az + c$ ($|a| = 1$), we are not surprised to find that this is also an isometry. In fact, if z and w are mapped on Z' and W',

$$|Z' - W'| = |az + c - aw - c| = |a||z - w| = |z - w|.$$

In our transformation of coordinate axes above, we *preserved* the *orientation* of the axes: that is, the sense of the rotation from $O'X_1'$ towards $O'X_2'$ is the same as that of OX_1 towards OX_2. If, however, we *reverse* the direction of *one* of the new axes (Fig. 42.2), say $O'X_2$, the point z with respect to OX_1, OX_2 now has the form

$$Z' = a\bar{z} + c \qquad (|a| = 1)$$

with respect to the new axes $O'X_1'$, $O'X_2'$.

Once again, if we suppose the coordinate axes to remain unchanged, and consider the mapping $Z' = a^{\bar{z}} + c$ ($|a| = 1$), we find that it is also an isometry, since

$$|Z' - W'| = |a\bar{z} + c - a\bar{w} - c| = |a||\bar{z} - \bar{w}| = |\overline{z - w}| = |z - w|$$

We shall find that these two isometries of the Gauss plane, which arise in this natural way by coordinate transformations, are the fundamental isometries of the Gauss plane, and there are no others.

Exercises

42.1 The X_1 and X_2-axes are interchanged, so that if $z = a + ib$, $Z = b + ia$ after the transformation. Show that the following composition of coordinate transformations produces the above result: $Z_1 = iz = -b + ia$, $Z_2 = \bar{z}_1 = -b - ia$, $Z = -Z_2 = b + ia$. Show also that the composition of these transformations is equivalent to $Z = i\bar{z}$.

42.2 Where are the new coordinate axes which induce the coordinate transformations

$$\text{(i)}Z = \bar{z} \ \text{(ii)}Z = i\bar{z} \ \text{(iii)}Z = -i\bar{z} + 1?$$

42.3 Find the coordinate transformation produced if the new system has its origin at the point $1 + i$, the new negative X_1-axis passes through O, and the new positive X_2-axis intersects the original positive X_2-axis. In the same circumstances, find the transformation if the new positive X_2-axis intersects the old positive X_1-axis.

43.1 The main theorem on isometries of the Gauss plane

Theorem *The set* $\mathscr{I}$ *of all isometries of the Gauss plane is composed of two classes* $\mathscr{I}_+$ *and* $\mathscr{I}_-$. *The class* $\mathscr{I}_+$ *consists of all isometries of the form* $z' = az + b$ $(|a| = 1)$, *and the class* $\mathscr{I}_-$ *of all isometries of the form* $z' = c\bar{z} + d$ $(|c| = 1)$.

We recall that an isometry is a one-to-one onto mapping of the Gauss plane which preserves the distance between a pair of points, and that such a mapping is also called a *congruent* or *rigid* transformation, or *motion*, if the plane is thought of as being moved over itself.

We have already seen that the mappings $\mathscr{I}_+$ and $\mathscr{I}_-$ are such that distance is preserved, but we have not checked that both are one-to-one onto mappings. In each case this is immediate, since if $z' = az + b$, z' is uniquely defined by z, and $z = a^{-1}(z' - b)$, so that, since $a \neq 0$, z is uniquely defined by z'. If $z' = c\bar{z} + d$, z' is uniquely defined by z, and $\bar{z} = c^{-1}(z' - d)$, so that $a \neq 0$, z is uniquely defined by z'.

We have some auxiliary theorems to prove before we establish the main theorem, Thm 43.1.

43.2 An auxiliary theorem

Theorem *Given two pairs of points* z_0, z_1 *and* w_0, w_1, *where* $|z_0 - z_1| = |w_0 - w_1| \neq 0$, *there is just one mapping of type* $\mathscr{I}_+$ *and just one of type* $\mathscr{I}_-$ *which maps* z_0 *onto* w_0 *and* z_1 *onto* w_1.

Proof. All that we have to do is to determine the constants a, b for a mapping of the first kind, and the constants c, d for a mapping of the second kind. Since we must have $az_0 + b = w_0$, and $az_1 + b = w_1$, where $|a| = 1$, subtraction gives us $a(z_0 - z_1) = w_0 - w_1$, which defines a, since $z_0 - z_1 \neq 0$, and also gives us a value of a for which $|a| = 1$. Knowing the value of a, we substitute, and find that $b = w_0 - az_0$. Hence a and b are both uniquely determined.

The proof that c and d are uniquely determined is very similar.

One of the things which interests us for any given mapping of the Gauss plane is whether points which are collinear are mapped into points which are collinear.

Definition. A *collineation* of the Gauss plane is a mapping which preserves collinearity, so that straight lines are mapped into straight lines.

A collineation need not be an isometry, as we see from the example of a central dilatation. But if we consider isometries, we have:

43.3 Isometries are collineations

Theorem *Every isometry of the Gauss plane is a collineation.*

Proof. In the real Euclidean plane we have a very powerful notion, derived from that of distance, namely the notion of a point lying on a line *between* two distinct points. If u, v and w are the complex numbers attached to three distinct collinear points, we know that v lies on the line joining the two other points, and between them, if and only if

$$|v - u| + |w - v| = |w - u|.$$

If under an isometry the points become u', v' and w' respectively, we have

$$|v' - u'| + |w' - v'| = |w' - u'|.$$

and since these points are also in the real Euclidean plane, the points represented by the complex numbers u', v' and w' must necessarily lie, in this order, on a line.

We deduce from this theorem that although Thm 43.2 tells us that there are at least two isometries which map z_0 on w_0 and z_1 on w_1, where $|z_0 - w_0| = |z_1 - w_1|$, each mapping maps a point of the line joining z_0 and z_1 onto a point of the line joining w_0 to w_1, and the effects of the mappings on points of the object line are identical.

43.4 Isometries and parallel lines

Theorem *An isometry of the Gauss plane maps parallel lines onto parallel lines.* (See Fig. 43.1.)

Proof. If P is a point in the Gauss plane, and l a line which does not contain P, the minimum distance of P from the line is well defined, and given by PR, where R is the foot of the perpendicular from P onto the line. Under an isometry, if P is mapped onto P', the line l onto a line l', and R onto R', the point R' lies on l', and $P'R'$ is the minimum distance of P' from l'. Hence $P'R'$ is perpendicular to l'.

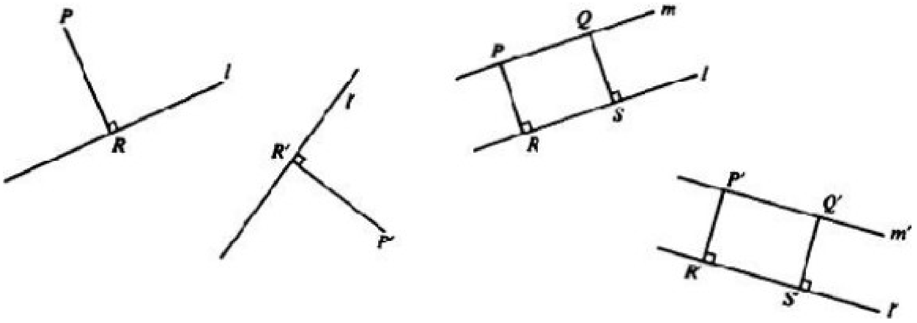

Fig. 43.1

Given two parallel lines *l* and *m*, take two distinct points *P* and *Q* on *m*, and let *R* and *S* be the respective feet of perpendiculars from *P* and *Q* onto the line *l*. Then $PR = QS$, and the isometry maps *l* and *m* into lines *l*′ and *m*′ which are likewise equidistant from each other, and therefore parallel.

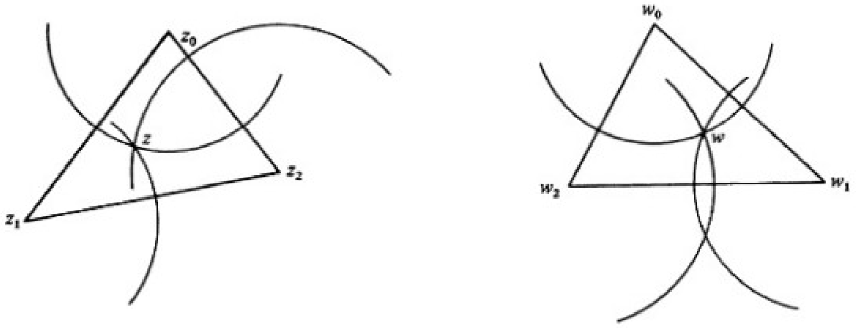

Fig. 43.2

Alternatively, and more rapidly, we may argue that if the maps *l*′ and *m*′ of *l* and *m* intersected at a point *P*′, the object of *P*′ would have to be a point lying on *l* and also on *m*, and by assumption these are parallel lines.

43.5 Determination of an isometry

Theorem *An isometry of the Gauss plane is uniquely determined by the assignment of the congruent map of a given triangle*. (See Fig. 43.2.)

Proof. We are given three distinct non-collinear points z_0, z_1 and z_2, and their respective images w_0, w_1 and w_2, where

$$|z_i - z_i| = |w_i - w_j| \ (i, j = 0, 1, 2).$$

We wish to show that the image of a point z distinct from the three given points z_i is uniquely defined under an isometry which satisfies the given conditions.

We may argue that a point is uniquely determined if its distances from three given non-collinear points are given. For the assignment of its distances from two given points determines the point as the intersection of two distinct circles, which intersect in two points, and the point also lies on a third circle, center at the third given point.

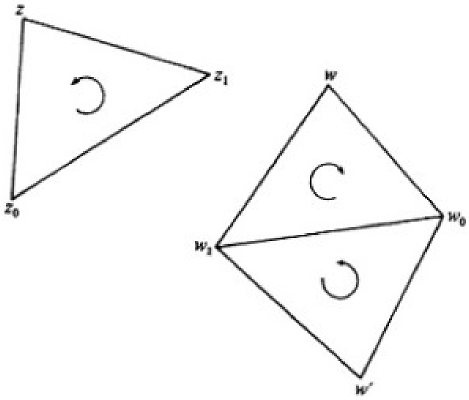

Fig. 43.3

This circle cannot pass through both points of intersection of the first two circles constructed, since its center would have to be collinear with the first two centers. Hence it passes through only one of the two points, and so the point is uniquely determined by its distances from three given non-collinear points.

Hence the image of z under an isometry is uniquely determined, since we are given the distances of z from the points z_i, and we are therefore also given the distances of the image w from the points w_i.

Another proof is indicated in Exercise 43.3.

43.6 An auxiliary theorem

Theorem *There are precisely two isometries of the Gauss plane which map two given points* z_0 *and* z_1 *onto two given points* w_0 *and* w_1, *where* $|z_0 - z_1| = |w_0 - w_1| \neq 0$. (See Fig. 43.3.)

Proof. We have already found two isometries which do this, in Thm 43.2, one of type $z' = az + b$ ($|a| = 1$), and the other of type $z' = c^{\bar{z}} + d$ ($|c| = 1$). We show that there are not more than two.

By an argument similar to the one used in Thm 43.5, we know that if a point z is not on the line joining the points z_0 and z_1, its image point w is determined as the intersection of two circles, one center w_0 and of radius $|z - z_0|$, and the other center w_1 and radius $|z - z_1|$. Hence there are two possible images of z. Call these points w and w'. By the preceding theorem, the assignment of w_0, w_1 and w as image points of z_0, z_1 and z determines the isometry uniquely, and similarly the assignment of w_0, w_1 and w' as the image points of z_0, z_1 and z determines the isometry uniquely. Hence there are at most two isometries which map z_0 on w_0 and z_1 on w_1, and since we know two isometries which do this, there are exactly two, and these are of the form $z' = az + b$ ($|a| = 1$) and $z' = c^{\bar{z}} + d$ ($|c| = 1$).

We have now proved our Main Thm 43.1, which we repeat here:

Main theorem on isometries of the Gauss plane. The set of all isometries $\mathscr{I}$ of the Gauss plane is composed of two classes $\mathscr{I}_+$ and $\mathscr{I}_-$. The class $\mathscr{I}_+$ consists of all isometries of the form $z' = az + b$ ($|a| = 1$), and the class $\mathscr{I}_-$ of all isometries of the form $z' = c^{\bar{z}} + d$ ($|c| = 1$).

Remark. We point out once again that the isometry which maps the points of the line joining z_0 to z_1 onto the points of the line joining w_0 to w_1 is unique. The fact that two distinct isometries can effect the mapping is only visible when we consider the mappings of points not on the line joining z_0 to z_1. We notice that the sense of rotation (w_0, w_1, w) is opposite to the sense of rotation (w_0, w_1, w') in the proof of the theorem above. One isometry, $z' = az + b$ ($|a| = 1$) *preserves* orientation, and the other, $z' = c^{\bar{z}} + d$ ($|c| = 1$) *reverses* orientation. Of course, we have not proved these statements as yet. The isometry $z' = az + b$ is called a *direct* isometry, and the isometry $z' = c^{\bar{z}} + d$ is called an *indirect* (or *opposite*) isometry.

Exercises

43.1 Find the isometries of the Gauss plane which map the point i onto the point O, and the point O onto the point 1. Which isometry also maps the point 1 onto the point $1 + i$? What is the image of the point 1 under the other isometry? Compare the orientations of the two image triangles.

43.2 l and m are two parallel lines, the points A, B lie on l, the points C, D on m, $AB = CD$, and AD intersects BC in E. Show that $AE = ED$, and $BE = EC$. Under an isometry, the points map into A', B', C', D' and E', and $A'B' = C'D'$, and $A'E' = E'D'$, while $B'E' = E'C'$. Prove that $A'B'$ must be parallel to $C'D'$, and deduce Thm 43.4.

43.3 Give another proof of Thm 43.5, using the theorem that under an isometry parallel lines map onto parallel lines. (If z is not on a side of triangle $z_0z_1z_2$, draw parallels to z_0z_1 and z_0z_2 respectively through z, intersecting z_0z_2 and z_0z_1 respectively in z'' and z'. Prove that w is uniquely determined by a reversal of this construction.)

43.4 Show that in cartesian coordinates a direct isometry is given by equations of the form

$$x' = x \cos \alpha - y \sin \alpha + p,$$

$$y' = x \sin \alpha + y \cos \alpha + q,$$

whereas an indirect isometry is given by equations of the form

$$x' = x \cos \alpha + y \sin \alpha + p,$$

$$y' = x \sin \alpha - y \cos \alpha + q,$$

Show that the inverse mappings which give (x, y) in terms of (x', y') have similar forms.

44.1 Subgroups

The axioms which determine a group have already appeared in §0.10. Here we give some more of the theory, for the reader who is not too familiar with the subject.

A *subgroup* of a given group G is a group whose elements lie in G, and whose operations are the same as those of G. For example, the rational numbers form a group under the operation of addition, and so do the integers, and the latter is a subgroup of the former. The set of even integers is a subgroup of the set of integers, and therefore also a subgroup of the set of rationals.

If we consider the set of all non-zero complex numbers, the operation now being *multiplication*, they form a group, with identity element the complex number 1, since any non-zero complex number has an inverse which is a complex number, the product of two non-zero complex numbers is also a non-zero complex number, and multiplication is associative. Within this group if we consider those complex numbers whose modulus is equal to 1, this set forms a subgroup, since $|z_1z_2| = |z_1|\ |z_2|$, and$|1/z| = |z|^{-1}$, shows that the product of two unimodular numbers is unimodular, and the inverse of a unimodular number is unimodular.

44.2 Conditions for a subgroup

Theorem *A non-empty subset H of a group G is a subgroup of G if and only if for every a, $b \in H$* (i) *b^{-1} and $ab \in H$, or* (ii) *$ab^{-1} \in H$.*

VI

MAPPINGS OF THE INVERSIVE PLANE

We now consider a larger group of mappings of the extended Gauss plane, named after Moebius, and to do so we extend the plane of the complex numbers by adjoining one additional point, which we call *the point at infinity*, and denote by the symbol ∞.

We stipulate that $1/z = \infty$, when $z = 0$, and calculations with the symbol ∞ will be performed according to the following rules:

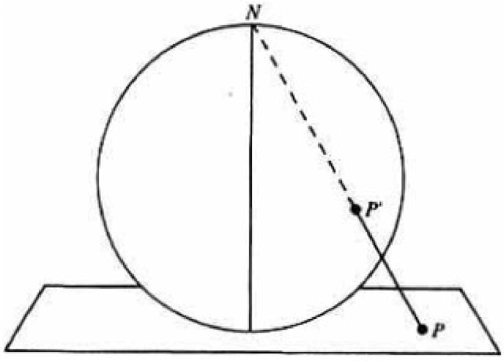

Fig. 52.1

For any finite complex number c,

$$c \pm \infty = \infty,\ c/\infty = 0,$$

and for non-zero c,

$$c \,.\, \infty = \infty,\ c/0 = \infty.$$

The expressions $\infty - \infty$, ∞/∞, $0 \,.\, \infty$ and $0/0$ are considered to be undefined.

Definition. The Gauss plane, with the point ∞ adjoined to it, is called *the inversive plane*.

Remark. If we recall that the complex number plane, the Gauss plane, is in one-to-one correspondence, by means of stereographic projection, with the surface of a punctured sphere, a sphere from which the point N of projection has been removed, all that we are doing now is to take the whole surface of the sphere as a map of the plane of complex numbers, adding the point N, to which we attach the symbol ∞ (Fig.52.1).

52.1 Moebius transformations

These are transformations of the inversive plane given by

$$z' = \frac{az + b}{cz + d},$$

where a, b, c and d are complex numbers with the restriction that

$$\Delta = ad - bc \neq 0.$$

The number Δ is called the *determinant* of the mapping.

We do not intend to give a detailed account of these mappings. Our purpose in this chapter is to develop the theory sufficiently to discuss the Poincare model of a hyperbolic non-Euclidean geometry. To do this we shall have to use many of the ideas we have introduced in preceding chapters.

52.2 The determinant of a Moebius mapping

Let us assume that in the expression $(az + b)/(cz + d)$, the number $c \neq 0$. Then we may write

$$\frac{az + b}{cz + d} = \frac{a}{c} - \frac{(ad - bc)}{c(cz + d)}.$$
